The use of v-*fms*-transformed NIH-3T3 cells in DNA-mediated gene transfer experiments offers certain advantages. The transformed cells multiply very rapidly, with shorter intervals between successive rounds of cell sorting, and they can be grown in medium lacking antimetabolites. The c-*fms* proto-oncogene product is a cell surface glycoprotein expressed by cells of the mononuclear phagocyte lineage and is related to the receptor for the macrophage colony-stimulating factor, CSF-1.[39] Although any transforming gene might function as a selectable marker in gene transfer experiments, we cannot exclude the possibility that the v-*fms* gene product in some way facilitates the expression of other myeloid genes. The subclone of NIH-3T3 cells used as recipients[19] may also be particularly suitable for such experiments, in that they contain small numbers of DMs. An attractive possibility is that transfected DNA sequences integrated into DMs in a small proportion of recipient cells, where they underwent spontaneous amplification. In the case of the stably amplified p67-expressing subclones, DMs were no longer detected, and the amplified sequences were chromosomally associated. There are several precedents for cells with DMs and unstably amplified genes to yield subclones with stably amplified genes, suggesting that genetic sequences in the DMs may become stably integrated in chromosomes.[4]

Although the plasmid containing the SM-FeSV provirus was also amplified in some of our clones, the levels of the v-*fms* gene product expressed at the cell surface were not increased. It is possible that the expression of high levels of the transforming glycoproteins is toxic to cells, resulting in a continued selection against their increased expression. Experiments performed with clones expressing gp150 indicated that revertants that segregated gp150 sequences were still morphologically transformed and expressed equivalent amounts of the v-*fms* gene product, even though they had lost copies of the SM-FeSV-containing plasmid. It seems likely, therefore, that at least some FeSV proviral DNA sequences were chromosomally integrated and were sufficient for morphological transformation.

Monoclonal antibodies have been developed that identify epitopes of molecules expressed on the plasma membrane of committed human myeloid progenitors [granulocyte-monocyte colony-forming units in culture (CFU-C)] and subsets of differentiated cells in the granulocyte and monocyte lineages.[26-29,32] The gp150 molecule is expressed by a proliferative subset of human CFU-C, as well as on normal marrow granulocytes and monocytes, at all recognizable levels of differentiation. Antibodies specific for gp150 do not bind normal B or T lymphocytes, platelets, erythrocytes, or erythroid progenitors defined by burst-forming units (BFU-E) or colony-forming units (CFU-E) in culture.[26,27]

The previously uncharacterized surface molecule immunoprecipitated by MY9 has an apparent mol wt of 67 kd. Although characterization of the molecule has been hampered by its relatively low levels of expression in human myeloid cells, transformants with amplified p67 expressed readily detectable levels of the polypeptide. High levels of fluorescence in flow cytometric studies were also observed after binding of the independently derived monoclonal antibodies L4F3 and L1B2,[32] providing evidence that these three antibodies recognize epitopes represented on the product of a single human gene. Antibodies specific for p67 bind all CFU-C and subsets of BFU-E and multipotent progenitors (CFU-GEMM), as well as myeloblasts, promyelocytes, myelocytes, and circulating monocytes. Binding is weak or absent on mature granulocytes, and not detected on lymphocytes, erythrocytes, and platelets.[28,32]

Specific antibodies to gp150 or p67 bind malignant cells from most patients with myeloid leukemias, but do not bind to leukemic cells of lymphoid origin.[26,28] This has led to applications of these antibodies in clinical diagnosis. Griffin et al, for example, have reported that 93% of myeloid leukemias can be identified from the binding of MY7 or MY9 antibodies.[28] Despite extensive studies of the distribution of gp150 and p67 on normal and malignant human myeloid cells, the functions of these surface molecules are unknown. It is clear that DNA-mediated gene transfer leading to gene amplification in transformed subclones should facilitate further characterization of these genes and their products and should provide a general method for isolating genes that encode a variety of cell-surface molecules.

Erythropoietin Kinetics in Rats: Generation and Clearance

By Stephen E. Steinberg, Joseph F. Garcia, Gary R. Matzke, and Jeanette Mladenovic

Detailed studies to analyze the early events of erythropoietin (Ep) secretion and clearance were performed in a rat model using a double antibody radioimmunoassay. Ep clearance was determined following intravenous injection of 1 mL of Ep-rich plasma, 1,080 mU/mL, obtained from phlebotomized rats. Analysis revealed a disappearance curve that conformed to a two-compartment model with an α half-life t ½ of 3.6 minutes and a β t ½ of 86 minutes. The volume of distribution was similar to the calculated plasma volume. In anephric animals, there was no change in the plasma clearance rate or the volume of distribution. Rapid Ep secretion was elicited by a single 15 mL/kg phlebotomy (hematocrit decrement 45% to 30%), so that levels reached 20 to 30 times baseline (524 ± 76 *v* 24 ± 7 mU/mL) at five hours, whereas they plateaued for at least 33 hours. The increase in the rate of secretion was geometric, from 9.9 mU/h baseline secretion to 429 mU/h. These data identify a very sensitive and rapidly responsive system for Ep modulation in the rat.

ERYTHROPOIETIN (Ep), a glycoprotein hormone of renal origin, stimulates red cell proliferation and differentiation in mammals in response to hypoxia.[1] As studies begin to demonstrate the potential therapeutic usefulness of this hormone in such disease states as chronic renal failure, an understanding of its pharmacokinetic properties becomes important.[2] In the past, detailed studies of Ep secretion and clearance have been limited by the lack of an assay sensitive enough to detect small changes in hormone levels.[3] The recent development and availability of a radioimmunoassay (RIA) for Ep have made these studies feasible.[4] We used the RIA in a rat model to determine the clearance rate of homologous Ep and to describe the early events of Ep secretion.

MATERIALS AND METHODS

Sprague Dawley rats, weighing 200 to 250 g, were used in all experiments. The source of Ep for clearance studies was plasma obtained from donor rats made severely anemic by every-other-day phlebotomy until the hematocrit reached 12% to 18%. The animals were then exsanguinated by aortic puncture, the heparinized blood was centrifuged at 2,500 rpm for 30 minutes, and the plasma was pooled. This Ep-rich plasma, although impure, represented a physiological form of the hormone that would be subject to endogenous clearance. Ep activity was assayed by the double-antibody RIA using a rat standard curve.[4,5] The intra-assay coefficient of variation was 8.4%. The Ep titer of the plasma used for all studies was 1,080 mU/ml. The bioactivity of the pooled Ep was demonstrated by intravenous (IV) injection of 1.0 mL into three animals followed by twice-daily determinations of the reticulocyte response. This resulted in a rise in reticulocyte count from a baseline of 0.6% ± 0.2% (SEM) to 5.8% ± 1.2% on day 3.

For clearance studies, animals were anesthetized with Innovar-Vet, and a polyethylene catheter was placed in the right atrium through the jugular vein for vascular access. One milliliter of Ep-rich plasma was given as an IV bolus. Serial 0.5-mL samples of heparinized blood were obtained through the central venous catheter from 30 seconds to two hours. Following each sample, volume was replaced with normal donor blood. Separated plasma samples were frozen at −20 °C until assayed by RIA. To study the effect of renal clearance on Ep disappearance, animals were anesthetized with Innovar-Vet and nephrectomized immediately before Ep-rich plasma was injected. This approach minimized volume changes related to diminished renal function.

To investigate Ep secretion, 12 animals underwent a 3-mL phlebotomy (15 mL/kg) after insertion of a central venous catheter as above. Immediate volume replacement with pooled plasma from normal donor animals (Ep = 18.5 ± 2.5 [SEM] mU/mL) resulted in a fall in hematocrit from an initial mean value of 45 ± 2.8 (SEM) to 29.5% ± 3.1%. Serial samples were again removed at intervals for Ep determination. An equivalent volume of normal donor blood adjusted to an hematocrit of 30 was reinstilled after each sampling to avoid hemodilution and hypovolemia.

Analyses. The plasma clearance data were analyzed by the following equation based on minimization of the residual sum of squares:

$$C(t) = Ae^{-\alpha t} + Be^{-\beta t}, \qquad [1]$$

where $C(t)$ is the concentration in serum at time t; A and B are the y intercepts, and α and β are the disposition rate constants obtained from the first and second phases of the plot of log serum Ep concentration *v* time. Initial estimates of the kinetic parameters were generated by standard curve stripping techniques.[6] Final estimates were obtained by nonlinear regression analysis with the program KINA on a Control Data digital computer (University of Minnesota, Minneapolis). The volume of distribution of the central compartment, the steady-state volume of distribution, the area under the serum concentration curve from zero to infinity, and the total body clearance were calculated by standard techniques.[6]

Stimulated secretion data were analyzed as follows. The baseline Ep serum concentration data were used to determine the unstimulated secretion rate (Ep Base) in 12 animals. The baseline Ep concentrations were assumed to reflect steady-state conditions, with the amount of Ep formed per unit of time equal to the amount of Ep removed during the same period of time. The concentration time curve from 0 to six hours was then analyzed on a Hewlett-Packard 9845 desktop computer by linear regression analysis and also by polynomial regression analysis from 0 to 60 hours [Equation 2]. The maximal Ep secretion rate (Ep max) was estimated from the ratio of the stimulated plateau Ep concentration (C_{STIM}) to baseline Ep concentration (C_{BASE}), assuming that total body clearance remained constant [Equation 3].

$$C(t) = m_1(t) + m_2(t^2) + b \qquad [2]$$

$$\text{Ep max} = [C_{\mathrm{STIM}}/C_{\mathrm{BASE}}] \cdot \text{Ep base} \qquad [3]$$

RESULTS

Erythropoietin clearance following IV bolus of 1 mL of Ep-rich plasma (1,080 mU) conformed to a two-compartment model (Fig 1 and Table 1). An initial rapid α disappearance, t½ = 3.6 minutes, was followed by a longer β phase, t½ = 86.4 minutes ($r = 0.97$, $P < .01$). The steady-state volume of distribution (4.27 mL) was similar to the plasma volume of these rats (5.1 mL).[7]

When the clearance study was repeated in anephric animals, similar results were obtained (Fig 2 and Table 1). Again the data conformed to a two-compartment model. When compared with clearance in normals, Ep clearance in anephric animals had an α phase that was several minutes longer, although the difference was not statistically significant. Although the β disappearance was prolonged due to the increased volume of distribution, total body clearance for anephric animals was slightly greater than normal, but the difference was not statistically significant (Table 1).

The early events of erythropoietin secretion are shown in Fig 3. In response to a single 15-mL/kg phlebotomy, a 21-fold increase in Ep levels was observed, from a baseline of 21 mU/mL to 525 mU/mL. Levels increased within minutes, began to plateau at five hours, and remained elevated for at least 33 hours. Using the homologous clearance data generated in the first portion of this study, the rate of secretion required to maintain the normal Ep level of ~20 mU/mL was calculated to be 53 mU/h. In response to a single phlebotomy, this basal rate of secretion doubled approximately every hour until it reached 450 mU/h at plateau.

DISCUSSION

These experiments detail the kinetics of Ep secretion and clearance, using homologous hormone, assaying levels by a sensitive RIA, and incorporating concurrent clearance data into a secretion model and vice versa. Following the bolus administration of EP-rich plasma, a two-phase clearance curve was obtained, as with previous studies.[8-11] Although studies using nonhomologous and/or biochemically altered Ep have yielded a slow equilibrium phase (ascribed to a large Ep molecule dispersing into a sizable extravascular space),[8,11] in this study the mean distribution phase t½ was 3.6 minutes. This rapid distributional phase might be expected in view of the volume of distribution, which was equivalent to the plasma volume of the animal.[7] This result is consistent with studies in sheep, also using homologous Ep, in which the Ep space was the same as the measured plasma volume.[12] In contrast, using a heterologous protein (sheep Ep injected into rats), Reissmann found that the volume of distribution approximated twice the plasma volume[8] It is possible that the initial rapid clearance of a foreign protein or of Ep bound to a heterologous carrier protein could yield an inordinately large volume of distribution, perhaps accounting for the discrepancy.[11]

Table 1. Erythropoietin (Ep) Clearance Data Following Intravenous Bolus of 1 mL of Ep-Rich Plasma

Clearance	Normal (Mean ± SEM)	Anephric (Mean ± SEM)	*P* Value
α t (min)	3.62 ± 0.51	7.80 ± 4.4	NS
β t (min)	86 ± 16	111 ± 21	NS
V_1 (mL)	1.87 ± 0.19	2.55 ± 0.45	NS
V_{ss} (mL)	4.27 ± 0.29	4.78 ± 0.23	NS
Total body (mL/min)	2.3 ± 0.31	2.48 ± 0.89	NS

Clearance data for 1 mL (1,080 mU) of erythropoietin in normal and anephric animals V_1, central compartment volume of distribution; V_{ss}, steady state volume of distribution.

Following the distribution phase, the second phase, that of plasma clearance, was linear from ten minutes to the end of the two-hour assay period, with a t½ of 86 minutes. Naets and Wittek, also using a biologic assay and homologous, exogenous Ep,[13] obtained a t½ of 1.5 hours Slightly longer t½s have been obtained in studies of Ep disappearance following the withdrawal of a hypoxic stimulus.[8,13,14] This difference may be due to ongoing Ep secretion, which persists even after withdrawal of the stimulus, thereby prolonging the apparent t½.[8] Other clearance data have been published, with Ep t½s ≤24 hours.[8-12,14-21] In addition to species variability,[10,12,15-17] there are several methodological differences between these studies and the present one. In some studies, the use of nonhomologous and/or iodinated serum Ep or even urinary Ep could have resulted in nonphysiologic clearances of "foreign" proteins or Ep aggregates.[8-11,15,16] As suggested by Emmanoel et al, it is possible that heterologous ^{125}I-Ep is metabolized differently than endogenous Ep, reflecting either the heterologous nature of the protein or the possibility that the iodination process, which renders the protein biologically inactive, also alters its clearance characteristics.[11] Although the use of ^{125}I-labeled Ep obviates confusion in the data due to ongoing endogenous production of the hormone,[11] this difficulty may also be resolved by incorporating the experimentally determined secretory rate into the calculations of Ep clearance.

There has been controversy regarding the role of the kidney in Ep clearance.[3] Early studies demonstrated that

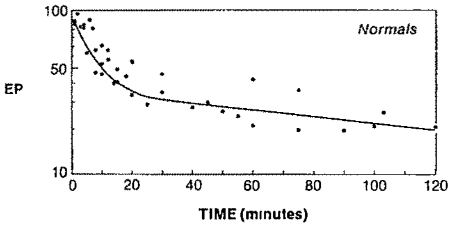

Fig 1. Clearance data following intravenous bolus of homologous Ep (1,080 mU) into ten normal rats.

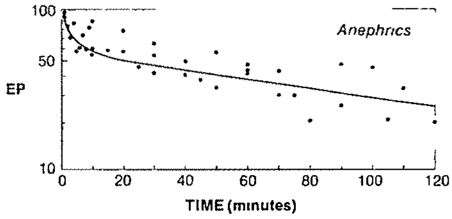

Fig 2. Clearance data following intravenous bolus of homologous Ep (1,080 mU) into ten anephric rats.

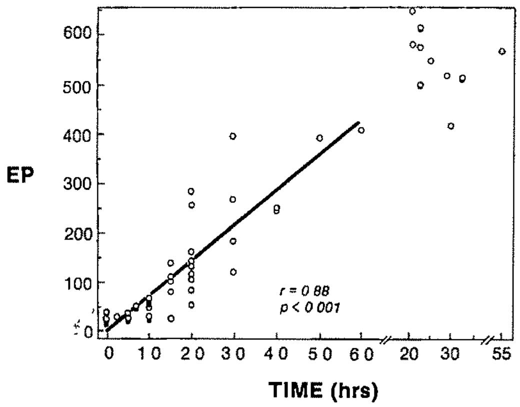

Fig 3. Ep levels (mU/mL) following 15-mL/kg phlebotomy in 12 rats.

urinary excretion parallels plasma concentration, but that urinary excretion constituted only a small portion of clearance.[10] Subsequent studies, nevertheless, have reported prolongation of Ep clearance after nephrectomy.[11,13-14,22,23] Recently, Emmanoel et al, using a highly purified erythropoietin, reported a very slight but statistically significant contribution of the kidneys to total body clearance [11] In the current study, nephrectomized animals had a slight, statistically insignificant prolongation of the plasma t½ and no change in the total body clearance. Mladenovic et al found no difference in Ep clearance in sheep both prenephrectomy and postnephrectomy.[12] It seems likely that the renal contribution to Ep clearance is less than 10%. It is possible that the loss of a renal contribution to Ep clearance and/or catabolism results in a compensatory increase in Ep clearance by other tissues.

In the past, it has not been possible to determine the rate of Ep secretion because of the requirement for accurate basal levels and the incorporation of plasma disappearance data.[3] In this study, the availability of the RIA and homologous plasma clearance data have allowed an accurate determination of the kinetics of Ep production. The normal Ep level of 19 mU/mL was maintained by a basal Ep secretory rate of 53 mU/h. When the animals were rapidly rendered anemic, the rate of Ep production increased geometrically, to at least nine times baseline levels. The Ep level rose almost instantaneously, reached a plateau at five to six hours and remained at this elevated level for up to 33 hours, suggesting persistent Ep secretion. The continuing Ep secretory response to the experimentally-induced anemia in this study may correspond to the clinical situation in which elevation of the Ep level is proportional to the severity of the anemia.[1] Although some studies of the time course of the Ep response are consistent with our data,[25,26] others have shown an early peak and rapid falloff of Ep levels by 24 hours.[24,25,27,28] These differences may be partially explained by differences in the various methods used to induce hypoxic stress (eg, phlebotomy, phenylhydrazine-induced anemia, hypoxia, and iron deficiency anemia). Miller et al and Cohen et al have further suggested that acid-base disturbances associated with both hypoxia and volume depletion could play a role in the early fall in Ep levels after stimulation.[27-29]

This study demonstrates the existence of a very sensitive system for Ep modulation in the rat. The immediate secretory response to anemic stress and the limitation of distribution to the plasma compartment work to initiate a rapid bone marrow response to changes in oxygen delivery. The relatively slow rate of clearance maintains stimulation of a slowly responsive end organ.

Cytogenetic and Immunophenotypic Analysis of Cell Lines Established From Patients With T Cell Leukemia/Lymphoma

By Stephen D. Smith, Rodman Morgan, Michael P. Link, Pamela McFall, and Frederick Hecht

Cell lines were established from five patients with T cell malignancies. Two patients had T cell lymphoblastic lymphoma (T-LL), whereas three patients had T cell acute lymphoblastic leukemia (T-ALL). Both T-LL cell lines expressed cell surface antigens characteristic of mid-thymocytes (Leu 2, 3, 6+). One T-ALL cell line also expressed this immunophenotype, one expressed suppressor/cytotoxic antigens (Leu 2+; Leu 3, 6−), and one expressed antigens of a mature but uncommitted T cell (Leu 4+; Leu 2, 3, 6−). Cytogenetic analysis showed that each cell line had 46 chromosomes with pseudodiploidy. The three T-ALL cell lines had only a few chromosome changes; one cell line had one deletion, another had two deletions, and the third had a translocation and two deletions (including loss of part of 9p). In comparison, both T-LL cell lines had complex chromosome changes, including most notably a rearrangement of band 14q11.2. The immunophenotypes and chromosome breakpoints showed patterns of interlock between the T-LL and T-ALL cell lines because common abnormalities occurred at six distinct chromosome sites. Cell lines with limited and specific chromosomal abnormalities are important because they can provide the basic material for molecular genetic studies that could elucidate the genetic mechanisms involved in neoplasia.

T-CELL LYMPHOID malignancies are a heterogenous group of diseases which express cell surface markers characteristic of thymus tissue In children and in young adults, two clinically similar T cell malignancies predominate: T cell acute lymphoblastic leukemia (T-ALL) and T cell lymphoblastic lymphoma (T-LL).[1,2] The T cell phenotype is seen in ~15% of cases of acute lymphoblastic leukemia, and patients initially often have a peripheral white blood count <100,000/μL, and a mediastinal mass. T-ALL shares some clinical features with T-LL; both diseases are associated with a mediastinal mass, are more common in males, and occur more commonly in adolescents and young adults.[1-3]

T-LL is arbitrarily distinguished from T-ALL by the lack of extensive bone marrow involvement (<25% marrow blasts).[4] Patients with T-LL generally have a more mature immunophenotype and a longer survival than do patients with T-ALL.[5-9] These distinctions suggest that the differences between these two diseases may be more than the degree of dissemination present at diagnosis.

It may be possible to separate T-cell malignancies more completely by chromosome analysis. Although karyotypes have been reported in >100 T cell malignancies, most cases have been found in patients with Japanese T cell leukemia or cutaneous T cell lymphoma.[10-13] In addition, only a few karyotypes have been reported from children with T-LL and T-ALL.[14] We recently established cell lines from two patients with T-LL and three patients with T-ALL. Both T-LL cell lines had complex chromosome changes that included a rearrangement of band 14q11.2. In contrast, the T-ALL cell lines had only a few chromosomal changes, yet abnormalities common to both T-ALL and T-LL were observed.

MATERIALS AND METHODS

Source of malignant cells The data discussed in this report were derived from five patients with T-LL or T-ALL. The protocol procedures were approved by the Medical Committee for the Use of Human Subjects in Research at Stanford University and informed consent was obtained from the parents and/or patients

The clinical and pathologic data on each patient are presented in Table 1 At initial examination, each patient had a large mediastinal mass, and the two patients with T-LL had a normal bone marrow aspirate and biopsy The patients with T-ALL had bone marrow involvement (M_3 bone marrow), and each had a white blood count >100,000/μL (with >80% circulating lymphoblasts) Malignant cells were collected from pleural effusion, bone marrow, or peripheral blood, and were anticoagulated with preservative-free heparin. Within four hours of collection, malignant lymphoid cells were separated by Ficoll-Hypaque density sedimentation and washed with "complete media" consisting of McCoy's 5A media supplemented with 15% fetal calf serum (FCS), penicillin (50 U/mL) and streptomycin (50 μg/mL) After a second washing, the malignant cells were separated into aliquots for cell culture experiments and immunophenotypic analysis.

Establishment and maintenance of cell lines The technique for culturing malignant T cells was a modification of our previously reported methods.[15,16] In brief, separated malignant cells were warmed to 37 °C in complete media and were pipetted to break up cell aggregates. The resultant single-cell suspension next was mixed with agar (0.3%) and plated onto 35-mm Petri dishes containing a feeder layer consisting of a combination of complete media, normal human serum (10%), and agar (0 5%) The Petri dishes were incubated at 37 °C in a Heraeus incubator gassed with 5% O_2, 6% CO_2, and 89% N_2. After 18 days of growth, individual colonies were aspirated from the agar, suspended in complete media (without agar), and transferred to Petri dishes containing a freshly prepared feeder layer. Cells were observed every three to five days and were passaged when the media appeared acidic (ie, when the phenolphthalein indicator turned yellow), or when the cell number approached 5 × 10^5 cells per milliliter. It was of particular importance that throughout the complete incubation period the cell culture

system contained no added mitogens, thiols, conditioned media, or interleukins.

Once steady cell growth occurred on the Petri dishes, cells (5×10^5 cells per milliliter) were passaged into flasks and thereafter grown in suspension culture in complete media. Initially, the flask contained a feeder layer; the volume of the feeder layer subsequently was reduced if cell viability could be maintained. Once the cells grew without a feeder layer, the oxygen concentration was gradually increased over a period of weeks until the cells had adapted to growth in an environment of 5% CO_2 in air. Each T cell line grew to a saturation concentration of $\sim 1 \times 10^6$ cells per milliliter and was routinely split three times per week. The average doubling of cells in log phase growth was calculated from daily counts. The cloning efficiency of the T cell lines was determined by mixing cells (1×10^5 cells per milliliter) with agar (0.3%) and replating them into a Petri dish containing a feeder layer. After 18 days of growth, colonies (cell groups containing >50 cells) were counted, and the cloning efficiency (CE) was calculated: CE = (number of colonies grown ÷ number of cells plated) × 100.

Characterization of cell surface antigens. Monoclonal antibodies to Leu-1 (Pan T), Leu-2a (T cytotoxic/suppressor), Leu-3a (T helper), Leu-4 (Pan T), Leu 5 (sheep erythrocyte receptor), Leu 6 (thymocyte), Leu 9 (Pan T), CALLA (common ALL antigen), and HLA-DR were generously provided by the Becton Dickinson Corporation (Mountain View, Calif). OKT_9 and OKT_{10} were purchased from Ortho Pharmaceuticals (Raritan, NJ). Surface immunoglobulin was detected by the $F(AB')_2$ fragment of fluorescein isothiocyanate (FITC)-conjugated goat anti-human immunoglobulin (TAGO, Burlingame, Calif). Cell surface antigens were identified by the binding of monoclonal antibody as detected by indirect immunofluorescence according to established methods.[17] Cells were analyzed for fluorescence staining with a FACS IV (Becton Dickinson Electronics Laboratory). The results were expressed as percentage of positive cells compared to background fluorescence when nonreactive myeloma protein was used in place of specific antibody.

Karyotype analysis. One drop of colchicine (Colcemid, GIBCO, Chagrin Falls, Ohio; 10 μg/mL in phosphate-buffered saline) was added to cells (log phase growth, 3×10^5 cells per milliliter) and incubated (37 °C, 10% CO_2 in air) for ½ to 1½ hours. The cells were pelleted by centrifugation, resuspended in 0.075 mol/L of KCl for ten minutes, fixed in fresh methanol-glacial acetic acid (3:1), and centrifuged. The cells were resuspended in fixative and left overnight at 4 °C. The next day, the cells were dropped onto glass slides and air dried, and the chromosomes were G-banded.[18] From each culture, at least 20 cells were analyzed microscopically, and karyotypes were prepared.

RESULTS

The clinical data on the five patients with T cell malignancies are shown in Table 1. These patients ranged in age from 8 to 52 years, and each patient had a large mediastinal mass when first examined. Cell lines were established from pleural effusions from the two patients with T-LL and from blood or bone marrow from three patients with T-ALL. One cell line (SUP-T2) was established from a patient at first examination (prior to therapy); the other four cell lines were established from patients at relapse.

The immunophenotyping studies of the T cell lines are listed in Table 2. Each cell line expressed pan-T markers (Leu 1, Leu 9) and at least two other T cell-specific antigens. In addition, each cell line was nonreactive with monoclonal antibodies against CALLA and HLA-DR and failed to express SIg. The two T-LL cell lines (SUP-T1, SUP-T4) and one of the T-ALL cell lines (SUP-T3) had cell surface antigens characteristic of the midthymocyte maturation stage.[7] These cell lines expressed Leu 2, Leu 3, and Leu 6 on the cell surface but lacked Leu 4. The SUP-T2 cell line had the cell surface characteristics of a suppressor/cytotoxic T-cell (Leu 2+, Leu 3−, Leu 6−). The K-T1 cell line was established in culture in 1978, and immunophenotyping on this cell line was first performed in 1982. The K-T1 cell line was Leu 4+, Leu 2−, Leu 3−, Leu 6−, indicating a mature but uncommitted immune profile. The antigen profile on the cell lines has been evaluated every six months, and it has remained stable without antigen gain or loss.

The growth characteristics of the five T cell lines are shown in Table 3. The T-LL cell lines (SUP-T1, SUP-T4) had a more rapid doubling time in suspension culture and a higher cloning efficiency in agar than did the T-ALL cell lines. The SUP-T2 cell line divided slowly in suspension culture and did not form colonies when resuspended in agar. The addition of supplemental sera, nutrients, and T cell growth factors did not enhance the cellular proliferation of the SUP-T2 cells.

The results of the cytogenetic analysis of the five T cell lines are shown in Table 4. Each cell line except cell line K-T1 was examined within the first six months of culture. When chromosome analysis without G-banding was initially performed on the K-T1 cell line, the translocation and deletions were not detected.[16] The T-ALL cell lines (K-T1, SUP-T2, SUP-T3) had comparatively few chromosomal changes whereas the T-LL cell lines (SUP-T1, SUP-T4) had a considerable number of complex chromosome aberrations.

†Cloning efficiency = (no. of colonies grown in agar ÷ no. of cells plated) × 100.

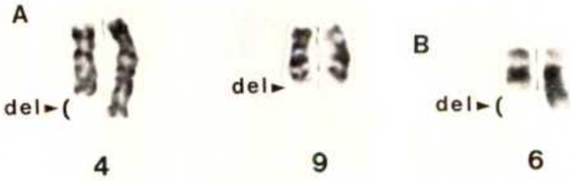

Fig 1. (A) Selected G-banded chromosomes depicting consistent chromosome defects found in cell line SUP-T3. Arrows indicate the site of del(4)(q31q35) and del(9)(q32q34). (B) Partial karyotype of cell line SUP-T2 analyzed by G banding. Arrow indicates the site of del(6)(q21q27).

The T-ALL cell line, SUP-T2, had a single chromosomal abnormality del 6 (q21q27), whereas the SUP-T3 cell line had two terminal deletions: del 4 (q31q35) and del 9 (q32q34) (Fig 1). These abnormalities were stable on repeat analysis and were the only abnormalities observed. The K-T1 cell line had an interstitial deletion on chromosome 2 del 2 (p16.3p22.1) and on chromosome 9 del 9 (p12p21.1) as well as a single translocation t(1;11) (p36.2;p13) (Fig 2). In addition, the K-T1 cell showed some signs of clonal evolution: a few cells lacked a chromosome 20 or gained a chromosome 11.

In comparison, the NHL cell line SUP-T1 was predominantly tetraploid and had multiple inversions and deletions. This cell line possessed two copies of an inversion on chromosome 2, inv(2) (q11p21), and a translocation involving the distal end of the long arm of chromosome 9, t(9;?) (q34;?); no normal copies of chromosome 2 or 9 were observed (Fig 3). The NHL cell line SUP-T4 had extensive chromosome numerical instability and a complex pattern of translocations, chromosomal loss, and marker chromosomes (Table 4, Fig 4).

Some of the chromosomal breakpoints in the T cell lines were common to more than one cell line (Table 5). One NHL cell line (SUP-T1) possessed changes that were found in each of the four other T cell lines. Both T-LL cell lines had a change at chromosome band 14q11.2. The SUP-T1 cell line had an inversion involving chromosome 14, inv(14) (q11.2q32), whereas the SUP-T4 cell line had a translocation involving the same band on chromosome 14, t(10,14) (q23;q11.2).

The SUP-T3 cell line, a mid-thymocyte cell like SUP-T1 and SUP-T4, had two chromosome abnormalities in common with SUP-T1. Both cell lines had a chromosome 4 deletion, del 4 (q31q35), as well as an abnormality at band q34 on chromosome 9. The SUP-T2 cell line had a single karyotype abnormality, del 6 (q21q27), and it shared the loss of chromosome 6 (q23q27) with the SUP-T1 cell line. Both the

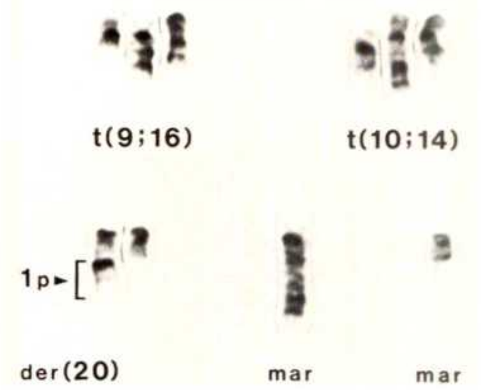

Fig 4. Selected G-banded chromosomes depicting consistent chromosome defects found in cell line SUP-T4. Arrows indicate the site of t(9;16)(qter → q12::q13 → pter), t(10;14)(q23;q11.2), der(20)t(1;20)(pter → p22::q13 → pter) and two marker (mar) chromosomes.

SUP-T1 and K-T1 cell lines had rearrangements involving proximal sites on chromosome 2. The SUP-T1 cell line had two copies of inv 2 (q11p21), whereas the K-T1 had a deletion involving chromosome 2, del 2 (p16.3p22.1). The T-LL cell line, SUP-T4, also shared a chromosome 9 abnormality with the K-T1 cell line. Both cell lines lacked chromosome 9 region p12 → p21.2 because the K-T1 had a chromosome 9 deletion, del 9 (p12p21.1), whereas the SUP-T4 cells had a translocation, t(9;16) (qter → q12::q13 → qter), resulting in the loss of the entire 9p arm.

DISCUSSION

Cell lines have been established from five patients with acute T cell malignancies; each cell line possessed specific chromosomal abnormalities. Although cytogenetic analyses were not performed on the patients' malignant cells, several lines of evidence suggest that the karyotype changes in the cell lines are representative of the chromosomal abnormalities in the patients' original malignant cells. First, prior to cell culture, the patients' malignant cells (in four of five cases) were characterized by a panel of monoclonal antibodies and biochemical enzyme markers.[19] The immunophenotype and biochemical enzyme profile of the patient's malignant cells were compared to the cell line established from an aliquot of these cells. The monoclonal antibody profile of the SUP-T1→T4 cell lines had the same basic immunophenotype as the patient's lymphoblasts, and full concordance existed for 48 of 52 paired antibody tests performed. In addition, each cell line had the same level of elevation of adenosine deaminase and reduction of nucleoside phosphorylase as the patient's malignant cells.[19]

Second, using DNA probes specific for the T cell receptor, each cell line had a rearrangement of the T cell receptor genes with respect to the germ line configuration (D. Faller and S.D. Smith, personal communication). The cell lines appeared unique and clonal, because each cell line had a different rearrangement pattern and no extra bands appeared on the gels. Third, the cell lines (except SUP-T4, which had chromosomal number instability) were chromosomally stable and specific karyotype abnormalities appeared in each cell analyzed. Finally, the karyotype of the cell lines established in our laboratory from patients with Burkitt's lymphoma or common ALL have good chromosomal concordance with patient's malignant cells analyzed prior to culture.

Karyotypic analyses of the T-cell lines revealed chromosomal breakpoints that were common to more than one cell line (Table 5). Six chromosome regions possibly are nonrandomly involved in T cell malignancies: 14q11.2; 4q31–35; 9q34; 6q23–q27; 2p22.1; and 9p12–p21.1. There was no strong correlation between the level of cellular maturation (as determined by monoclonal antibodies) and these six chromosome regions. The abnormality at bands p12 through p21.1 on chromosome 9 was found in two mature T cell lines (Leu 4+) but not in the other T cell lines (Leu 4−). Further studies comparing the karyotype and immunophenotype in malignant T cells are needed to determine the incidence and significance of these associations.

Table 5. Common Band(s) Involved in the Chromosome Rearrangements of Five T Cell Lines

SUP-T1	T-LL	14q11.2	4q31-q35	9q34	6q23-q27	2p22.1*	
SUP-T4	T-LL						9p12-p21.1†

SUP-T2	T-ALL						
K-T1	T-ALL						

*Both cell lines have rearrangements involving proximal bands on chromosome 2, band p22.1 (K-T1) and band p21 (SUP-T1).

†Both cell lines lacked chromosome 9 region p12→p21.1.

Both T-LL cell lines possessed a rearrangement involving chromosome 14 band q11.2. The inversion in chromosome 14, inv(14) (q11.2q32.3), appears specific for neoplastic T lymphocytes and has been found in T-CLL, T-cell lymphoma, and a lymphosarcoma cell line.[9,20,27] In addition, reciprocal translocations between the region of q11.2 of chromosome 14 and chromosomes 10, 11, and 14 have been observed in T-ALL, T-LL, and T-cell malignancies from patients with ataxia telangiectasia.[13,22] These observations led investigators to suspect that this chromosome band may be adjacent to genes that control cellular proliferation in general or ones that control specific aspects of T cell growth. Subsequent investigations determined that the gene for the α chain of the T cell receptor is located on chromosome 14 band 11.2.[23,24] Thus, T cell chromosomal translocations may be analogous to B cell malignancies that possess translocations involving the immunoglobulin heavy (or light) chain locus and the *myc* oncogene.[23,25]

The functional significance of the other chromosomal abnormalities that occurred in more than one T cell line are less well defined (Table 5). Two cell lines had a deletion of the long arm of chromosome 4 with a breakpoint at band 4q31. This breakpoint is adjacent to the gene for the T cell growth factor (interleukin 2, IL-2) which is reported to be located at band q26 through q28 on chromosome 4.[26] The cell lines have been established and maintained without supplemental IL-2, but T cell lines may produce IL-2.[27] In T lymphocytes which possess IL-2 receptors, IL-2 gene activation may be associated with excessive proliferation and/or neoplasia by an autocrine loop mechanism.[28]

Abnormalities involving chromosome 9 were observed in four of the five T cell lines. Two cell lines had an irregularity involving the distal end of the long arm of chromosome 9, whereas two other cell lines had an interstitial deletion of the short arm (Tables 4 and 5). Structural rearrangement on chromosome 9 are seen in ~20% of the cases of T cell malignancies and in many of the breakpoints on the short-arm cluster near band 9p21.[10,29] Nonrandom loss of chromosome material at 9p21 was recently observed in the karyotype from six of eight children with ALL with lymphomatous features.[30] Moreover, loss of 9p− may have clinical significance because the subgroup of ALL patients with this deletion appear to have a grave prognosis.[31] Breakpoints on the long arm of chromosome 9 tend to occur near band q34, the site of the *abl* oncogene.[10,31-34] The *abl* oncogene has been shown to be expressed in CML, AML, T cell lines, and malignant cells from patients with T-ALL.[34-36]

One T-ALL cell line (SUP-T2) has a single chromosome abnormality, a deletion of the long arm of chromosome 6, del 6 (q21q27). The 6q- abnormality is a chromosomal change observed in hematopoietic malignancies; it has been commonly identified in cases of diffuse large cell lymphoma, Japanese adult T cell leukemia and Sézary syndrome.[11,32,37-39] In pediatric malignancies, the 6q- abnormality occurs in ~10% of cases of common ALL and T cell ALL.[40,41] In these reports, the breakpoints in the long arm of chromosome 6 varied from band q15 to band q25 but tended to concentrate at band 6q21. The *myb* oncogene has been localized to chromosome 6 band q22-24, and expression of this oncogene routinely occurs in hematopoietic malignancies.[35,42] Another oncogene, n-*myc*, may also be expressed in T cell malignancies. Two cell lines had rearrangements involving proximal bands on chromosome 2 that were adjacent to or involved the site of the *n-myc* oncogene, which has been localized to chromosome 2 band p22p24.[43]

*Proposed location of T cell lymphoma/leukemia-1 oncogene.[23]

Each of the five T cell lines had at least one chromosome breakpoint that involved a band reportedly possessing a proto-oncogene (Table 6).[34,44] Of the six chromosomal abnormalities seen in more than one T cell line, three are close to an oncogene site, and oncogene expression secondary to chromosomal breaks may be involved in the genesis of T cell neoplasia. An apparent inverse relationship exists in the cell lines between the number of oncogene sites involved and the length of the doubling time of the cell lines in vitro.

Chromosome weak points may be unmasked by procedures that stress cells growing in suspension cultures. These chromosomal fragile sites may readily break under the biologic stress of growth media containing: (a) low folic acid, (b) aphidicolin, or (3) caffeine.[45-47] Of the 21 chromosome breakpoints in the five T cell lines, 11 were located at or near fragile sites (Table 7). Chromosome changes at fragile sites may have occurred in the malignant cells in vivo (prior to

Derived from data in ref 48.

culture) or they may be secondary to the stress of proliferation in vitro. In the T cell lines reported, six specific chromosomal abnormalities occurred in more than one cell line. The fact that only one of these abnormalities (4q31) occurred at a fragile site supports the hypothesis that the fragile site changes occurred in vivo.

Structural karyotypic aberrations in human malignancies may be primary changes associated with cancer cell growth or may be secondary to excessive cellular proliferation alone. Recently, Mitelman reported a restricted number of chromosomal regions may be implicated in the etiology of human malignancies.[48] By using a registry of malignancies karyotyped with banding studies, he found 54 common cancer chromosome abnormalities, which were present in >90% of 3,844 registry cases.[49] The 54 reported common cancer chromosome abnormalities were restricted to 61 bands. Of the 21 chromosome breakpoints in the five T cell lines presented, seven were located at or adjacent to sites of common cancer chromosome changes (Table 8).

Thus, many of the karyotype changes in the T cell lines are associated with chromosomal abnormalities commonly observed in cancer. In addition, chromosome breakpoints are close to oncogenes or genes that may control specific aspects of T cell growth (IL-2 α chain of the T cell receptor). Because cell lines can proliferate indefinitely, they may provide the basic material for investigations defining the biologic significance of specific chromosome changes.

NOTE ADDED IN PROOF

Recently, a cell line (SUP-T5) was established from a patient with T-LL which possessed a unique translocation between chromosome 7 and chromosome 9: t(7;9)(q34;q34.3).[51] Upon re-examination of the karyotypes of the cell lines reported here (with specific attention to chromosomes 7 and 9), a t(7;9)(q34;q34 3) was found in the SUP-T1 cell line while a t(7,9)(q34;q32) was found in the SUP-T3 cell line Thus, band q34 on chromosome 7 may be an additional common chromosome breakpoint in T cell malignancies.

Spontaneous Tumor Cytolysis Mediated by Inflammatory Neutrophils: Dependence Upon Divalent Cations and Reduced Oxygen Intermediates

By Alan Lichtenstein

The role of divalent cations and reactive products of the respiratory burst were investigated in spontaneous tumor lysis mediated by inflammatory neutrophils (PMNs). Murine peritoneal PMNs, obtained five hours after intraperitoneal injection of bacteria, conjugated and lysed teratocarcinoma cells in chromium release and single-cell cytotoxicity assays. The presence of extracellular magnesium was required and was sufficient for tumor cell binding to PMNs. Postbinding lytic events depended upon the simultaneous presence of extracellular calcium and magnesium. Catalase and superoxide dismutase inhibited postbinding lytic events, indicating that production of reduced oxygen moieties was important. Scavengers of hydroxyl radicals could inhibit tumor cell binding, but none could affect postbinding lytic events. Neither could inhibitors of myeloperoxidase decrease tumor lysis. The ability of conjugating PMNs to lyse their bound targets correlated with their reduction of nitro blue tetrazolium (NBT). Optimal concentrations of phorbol myristate acetate (PMA) markedly increased the NBT positivity of PMNs and the killing of bound tumor cells. Even with optimal stimulation of the respiratory burst, however, there was still a significant number (19%) of bound targets that escaped lysis, suggesting active resistance to oxygen-mediated tumor cell injury.

© 1986 by Grune & Stratton, Inc.

PREVIOUS STUDIES have demonstrated that neutrophils (PMNs) must be activated in vitro before they can exert significant extracellular tumor cytotoxicity.[1-5] Almost all of these studies, however, have assayed peripheral blood (PB) PMNs; inflammatory PMNs may be better suited for tumor cytolysis. Our previous studies[6-8] support this hypothesis. Peritoneal PMNs, elicited as part of an acute inflammatory response to injection of killed bacteria or thioglycolate, exerted significant and rapid lysis of a variety of murine or human tumor cells [6,7] Simple binding to tumor cells was not sufficient because lysis also depended on temperature-dependent postbinding events.[8] Lysis was initiated rapidly and completed within 30 to 45 minutes after membrane contact with tumor cells.[6,7]

The activation of PMNs as they migrate into sites of inflammation may explain their acquired ability to exert spontaneous tumor lysis. In particular, exposure to chemotactic peptides[4,9] or leukotriene B_4[10] markedly enhances the ability of PMNs to undergo a respiratory burst upon subsequent activation, with the resulting production of huge quantities of reactive oxygen intermediates (ROIs). As previously demonstrated,[11,12] these reduced oxygen species are capable of inducing significant tumor cytolysis. Thus, we initiated these studies to assess the role of oxygen metabolites in spontaneous tumor lysis mediated by inflammatory PMNs. The results confirm that lysis is due to the concomitant production of hydrogen peroxide (H_2O_2) and superoxide (SO).

In addition to a chromium release assay (CRA), we used a cytotoxicity assay, which enables visualization of effector–target interactions at the single cell level[8] and allows a separation of PMN tumor lysis into two distinct phases: tumor cell binding and postbinding lytic events. A previous report detailed the disparate temperature requirements for each phase.[8] The current study further supports the hypothesis that the two phases are under separate regulatory control: magnesium ions were required for tumor cell binding whereas calcium as well as magnesium ions were required for postbinding lytic events.

MATERIALS AND METHODS

Mice Female C3HeB/FeJ mice, 6 to 8 weeks of age, were obtained from the Jackson Laboratory (Bar Harbor, Me) and were rested in our vivarium for one week before initiation of an experiment.

Tumor. The murine ovarian teratocarcinoma (MOT)[13] is maintained by weekly intraperitoneal (IP) passage in C3HeB/FeJ mice.

Drugs. *Corynebacterium parvum (C parvum,* strain CN6134) was purchased from Burroughs Wellcome (Research Triangle Park, NC). Thioglycolate broth was obtained from Difco (Detroit, Mich) and was injected IP as a 10% solution The following drugs were purchased from SIGMA (St Louis): EDTA, EGTA, agarose, nitro blue tetrazolium (NBT), superoxide dismutase (SOD), catalase, phorbol myristate acetate (PMA), sodium benzoate, D-mannitol, potassium cyanide, L-tryptophan, thiourea, ethylene glycol, L-histidine, methimazole, and aminotriazole. Dimethyl sulfoxide (DMSO), calcium chloride, and magnesium chloride were obtained from Mallinckrodt (St Louis), and sodium azide was obtained from J.T. Baker Chemicals (Phillipsburg, NJ) PMA was stored in ethanol at −20 °C. Several lots of catalase and SOD were tested until we identified reagents that lacked contamination by the other enzyme.

Treatment and lavage of mice. Mice were injected IP with a 0 2-mL solution containing 1,400 μg of *C parvum* or 0 4 mL of a 10% solution of thioglycolate. Five hours after being injected, the mice were killed Their peritoneal cavities were lavaged by rapid injection of 10 mL of cold phosphate-buffered saline (PBS) Peritoneal fluid was withdrawn and reinjected twice more. After washing, peritoneal exudate cells (PECs) were counted, resuspended in media, and used directly in chromium release assays, or were fractionated on Percoll gradients in preparation for conjugate and single-cell cytotoxicity assays. Viability of PECs after lavage was always >97%

CRA. Targets were radiolabeled by incubating 1×10^7 MOT cells with 50 μCi of ^{51}Cr for one hour at 37 °C in a shaking water bath in RPMI medium supplemented with 10% fetal calf serum

(FCS, Reheis, Ariz) PECs (0 1 mL) were mixed with 1 × 10^4 radiolabeled target cells (0.1 mL) at different effector–target (ET) cell ratios in microtiter plates. Samples were run in quadruplicate. After four hours of incubation at 37 °C in a 5% CO_2 atmosphere, plates were centrifuged (1,200 rpm for ten minutes), and 0.1 mL of supernatant was removed and counted in a gamma counter Percentage of specific lysis was determined by: cpm experimental group − cpm minimal release/cpm maximal release − cpm minimal release × 100 Minimal release was determined by incubating targets in medium alone for four hours. Maximal release was determined by adding HCl to a concentration of ~1 mol/L. Data are presented as percentage of specific release at different ET ratios, mean ± SD of three to four separate experiments We have previously documented that significant in vitro lysis of MOT targets, mediated by PECs obtained 12 hours after IP injection of *C parvum* or thioglycolate, is due to the action of PMNs [6,7]

Percoll gradient fractionation of PECs Percoll fractionation of PECs (obtained five hours after IP injection) was performed as previously described.[6,7] In brief, a self-generating Percoll gradient was formed by mixing 1 mL of PECs (1.5 × 10^7/mL in RPMI and 10% FCS) with 8 mL of 70% Percoll (Pharmacia, Piscataway, NJ) in 10-mL high-speed centrifuge tubes. Tubes were spun at 60,000 g for 20 minutes at 15 °C in a Beckman high-speed centrifuge with a Ti-50 fixed angle rotor The PMN-enriched, macrophage-depleted cell fraction was found in a band corresponding to a density range of 1 075 to 1.090. Viability was always >94%. PMN-enriched fractions contained 92% to 97% PMNs, 3% to 8% lymphocytes, and 0% to 1% macrophages

Single-cell cytotoxicity assay (SCCA) The SCAA was performed as a modification of the method of Grimm and Bonavida[14] as previously described [6–8] In brief, PECs were first fractionated on the self-generating Percoll gradient and were then washed and resuspended to 2 × 10^6/mL in RPMI and 1% FCS. MOT targets were washed and resuspended to 2 to 10 × 10^6/mL (depending upon desired ET ratio) in RPMI and 1% FCS All experiments depicted were performed at ET ratio of 1:5 unless otherwise indicated. Targets and effectors were kept separately at 30 °C for five minutes prior to conjugation. Effectors (0.15 mL) were then mixed with targets (0 15 mL) in 10 × 75 borosilicate tubes and incubated at 30 °C for ten minutes. The tubes were centrifuged at 200 g for five minutes, and the supernatant was decanted. After 0.05 mL of RPMI and 1% FCS was added, the cell pellet was gently resuspended by slowly drawing the mixture into a pipette tip (50-μl MLA pipette) and slowly expelling it back into the tube Molten agarose at 39 °C was quickly added (50 μL) to each tube and mixed by brief rotation. The agarose–cell mixture was then spread onto agarose-coated slides. The slides were then submerged in RPMI and 1% FCS for incubation at 37 °C in a 5% CO_2 incubator. After one hour, slides were immersed in 0.2% trypan blue for five minutes to stain dead cells and were rinsed in 0 3% formalin until excess stain was removed. Slides were kept in 0.3% formalin until examination

To identify effector cells, trypan-stained slides were flooded with safranin for 90 seconds and then immersed in water for 60 seconds to remove excess stain When examined under oil immersion, living cells stain orange and dead cells stain purple. Percentage of conjugation was calculated as follows number of conjugates/total number of PMNs (bound and unbound) × 100 Percentage of killing was calculated as follows: number of dead targets in conjugates/total number of conjugates × 100. At least 200 PMNs/slide were examined and enumerated to determine percentage of conjugation and percentage of killing The slides were run in triplicate, and the standard deviation (SD) was always <5% of the mean values. The data is presented as mean ± SE of three to four separate experiments.

We have previously demonstrated[6–8] that all conjugates consist of either one target bound to one PMN (90%) or one target bound to two or more PMNs (10%). Control slides containing targets alone consistently demonstrated >96% viability during a one-hour incubation In addition, unbound targets as well as bound and unbound PMNs consistently demonstrated >95% viability during the assay Thus, on experimental slides, loss of viability (trypan positivity) occurred only in the bound target cell population.

Cytotoxicity assays with enzyme inhibitors and scavengers. PMNs and targets were individually suspended in media containing different concentrations of inhibitors or scavengers and were kept in these solutions for five minutes at 30 °C. In the CRA, PMNs and targets were then mixed in microtiter plates, centrifuged, and incubated for four hours In the SCCA, PMNs and targets were mixed for ten minutes, centrifuged at 200 g for five minutes, the supernatants were decanted, and new media and agarose containing the same concentrations of inhibitors or scavengers were added. Thus, PMNs were in contact with inhibitors/scavengers before conjugation and remained in contact until termination of the incubation. In separate control slides, exposure of tumor cells alone (no PMNs) to these concentrations of inhibitors/scavengers did not affect viability In CRAs, the spontaneous release of radioisotope from targets was not affected by these concentrations of inhibitors/scavengers.

Pretreatment with cyanide PMNs and MOT targets were suspended at 2 × 10^6/mL in RPMI media, 1% FCS, and varying concentrations of potassium cyanide (at pH = 7.4) for incubation at 4 °C After 30 minutes, the cells were washed four times, counted, and resuspended for cytotoxicity assays. Viability after cyanide pretreatment was always >95%.

Calcium pulse experiments The calcium pulse technique was used as previously described.[15] In brief, PMNs and tumor targets were mixed in the presence of EGTA (1 mmol/L), which allowed conjugation to occur normally but prevented initiation of lysis by chelating calcium Calcium chloride (10 mmol/L) was then added to initiate lysis in the presence or absence of the scavenger in question Incubation was continued at 37 °C for one hour before examination of PMN-target conjugates for determination of percentage of binding and percentage of killing. Control slides on which cells were conjugated and resuspended in EGTA *without* calcium supplementation were examined to ensure that the chelation of calcium prevented tumor cytolysis

Use of NBT in SCCAs The reduction of NBT to dark blue formazan deposits was used to detect PMNs actively producing reduced oxygen moieties. After PMNs and targets were mixed and centrifuged, the supernatant was decanted Fifty lambda of 0.1% NBT (in RPMI) was added to the cell pellet. An equal volume of molten agarose was then added before the cell mixtures were plated on slides to bring the final concentration of NBT to 0.05%. Slides were then immersed in media containing 0.05% NBT for the one-hour incubation at 37 °C All slides containing NBT were kept protected from light until examination. Staining with trypan and safranin after completion of incubation was performed as described above

Determination of optimum concentration of PMA for PMN stimulation Peritoneal PMNs were obtained five hours after IP injection of *C parvum* and were stimulated with PMA. Hydrogen peroxide (H_2O_2) production was measured by the loss of fluorescence from scopoletin [16] Hydrogen peroxide produced by PMA-stimulated PMNs was plotted against a standard curve of scopoletin reduction, which was generated by sequential additions of 1 nmol of reagent grade H_2O_2 in the presence of 10^{-4} mol/L of scopoletin (SIGMA) and 1 μg/mL of horseradish peroxidase (SIGMA) Under these conditions, 10^{-7} mol/L of PMA stimulated the greatest release of H_2O_2 (9 2 nmol/L of H_2O_2/10^6 PMNs per five minutes).

Stimulation with PMA in SCCA. After PMNs and targets were mixed and centrifuged, the supernatant was decanted. Fifty lambda

*PECs were obtained five hours following IP injection of 1,400 μg of formalin-killed bacteria. PECs were then fractionated on self-generating Percoll gradients resulting in a PMN-enriched fraction (fraction 4) and a PMN-depleted fraction (fraction 1). PECs from both fractions were used as effectors in a 4-h chromium release assay against MOT targets. In addition, PECs of fraction 4 (PMN-enriched) were used as effectors in the single-cell cytotoxicity assay.

of PMA (2×10^{-7} mol/L) was added to the cell pellet and an equal volume of molten agarose was added to give a final concentration of 10^{-7} mol/L PMA (10^{-7} mol/L) was also present during the one-hour incubation

Statistics The *t* test was used for all *P* value determinations.

RESULTS

Inflammatory neutrophils spontaneously lyse tumor targets. PECs, obtained five hours following IP injection of formalin-killed bacteria contain 93% ± 4% PMNs, 4% ± 1% lymphocytes, and 3% ± 1% macrophages (mean ± SD for four experiments). Tumor lysis mediated by these PECs is due to the effects of PMNs (Table 1). First, PECs enriched for PMNs and depleted of macrophages (fraction 4 PECs) are effective, whereas cell populations depleted of PMNs (fraction 1 PECs) are ineffective in exerting cytolysis. Second, only peritoneal PMNs were capable of binding and lysing targets in the SCCA. Although lymphocytes could bind, they could not lyse targets during the incubation period. Third, pretreatment with anti-theta or anti-asialo-GM$_1$ antibodies and complement, which effectively depleted PECs of T lymphocyte [responsiveness to phytohemagglutinin (PHA) and Concanavilin A (Con A)] and NK lymphocyte (lysis of YAC-1 targets) activity, did not affect the lysis of MOT targets (data not shown). These data are consistent with our earlier studies[6–8] documenting spontaneous tumor lysis by inflammatory PMNs.

The role of divalent cations in PMN-mediated tumor cytolysis. Initial experiments using the CRA demonstrated that the addition of EDTA (1 mmol/L) or EGTA (1 mmol/L) significantly suppressed PMN-mediated cytolysis (Table 2). We then used the SCCA, which enabled an independent evaluation of tumor cell binding and postbinding lytic events. When effector PMNs and targets were mixed in 1 mmol/L of EDTA, but not EGTA, significant inhibition of tumor cell conjugation occurred (Table 2) Because the former chelates calcium and magnesium and the latter chelates only calcium, these data indicated a requirement for magnesium ions in the tumor-binding phase of lysis. Table 2 also demonstrates that inhibition of binding was

reversed by the addition of 10 mmol/L of exogenous magnesium, indicating that EDTA did not cause an irreversible nonspecific suppression of PMN function. Inhibition of binding by EDTA could not be reversed by exogenous calcium (Table 2), further indicating calcium is not required for binding.

Because EGTA did not affect the binding step but significantly suppressed chromium release (Table 2), the data suggested that calcium was required for postbinding lytic events. To test this hypothesis, PMNs and targets were first mixed for ten minutes in EGTA. Because free magnesium was present, binding to tumor cells occurred normally (Table 3). After centrifugation, conjugates were resuspended in agarose-media with the identical concentration of EGTA present. The percentage of killing was significantly suppressed in this group (line B, Table 3) indicating a requirement for calcium during the postbinding lytic events. When these events occurred in EGTA with excess calcium added (line C), the percentage of killing was comparable to that of the control group (line A), indicating that EGTA did not irreversibly affect PMNs to prevent them from lysing targets. Tumor cells incubated alone (no PMN effectors) in EGTA (1 mmol/L) with or without excess calcium (10 mmol/L) maintained viability >93%

To assess the role of magnesium during postbinding lytic events, PMNs and tumor cells were mixed in EGTA, which allowed normal binding but prevented lysis from occurring (by chelating calcium). After centrifugation, conjugates were resuspended and incubated in agarose-media to which different supplements were added (Table 4). In line A, excess calcium was added and significant lysis occurred. In line B, the incubation was performed in EDTA and lysis was completely inhibited, indicating that calcium or magnesium or both are required for postbinding lytic events. Lines C, D, and E in Table 4 demonstrate that both cations are required for the lytic events because only when both are replaced in the incubation media is the percentage of killing normalized. Control slides of tumor cells alone (no effectors) incubated in EDTA (1 mmol/L) with calcium (10 mmol/L) or magnesium (10 mmol/L) demonstrated viability >94%.

Tumor lysis depends upon hydrogen peroxide and superoxide production by PMNs. We next investigated the role of oxygen metabolites by adding enzyme inhibitors of ROIs to the cytotoxicity assays. Addition of catalase or SOD inhibited tumor lysis in a concentration-dependent fashion (Table 5). There was no inhibition of tumor cell binding, but postbinding lytic events were significantly inhibited. Furthermore, heat-inactivated enzymes were not inhibitory, ruling out a nonspecific toxic effect on PMNs. Tumor cells incubated alone (no effectors) with catalase and/or SOD maintained a viability >92%. Inhibition of lysis achieved by adding both enzymes together was significantly greater than it was when either one was used separately (Table 5). This suggested that hydroxyl radicals, formed by a reaction between superoxide and H_2O_2 (Haber-Weiss reaction) were important mediators of tumor lysis. To test this hypothesis, several scavengers of hydroxyl radicals were added to CRA or single-cell cytotoxicity assays Histidine (0.25 to 25 mmol/L, tryptophane (0.25 to 25 mmol/L), and ethylene glycol (0.32 mol/L) had no effect on percentage of specific lysis, percentage of binding or percentage of killing of targets (data not shown). Thiourea suppressed cytotoxicity in the

CRA; however, this was due solely to an inhibition of tumor cell binding (Table 6). Killing of bound tumor cells was not affected by these concentrations of thiourea. Mannitol, DMSO, and benzoic acid all suppressed chromium release in a concentration-dependent fashion. These drugs markedly inhibited tumor cell binding by inflammatory PMNs so that their effects on postbinding lytic events could not be assessed. We therefore added the drugs to PMN–tumor cell mixtures that had successfully completed the conjugation step (Table 7, calcium pulse technique). Neutrophils and targets were conjugated in EGTA (line C, Table 7), which allowed normal tumor cell binding but prevented lysis. Conjugates were then incubated in excess calcium with (line E) or without (line D) the inhibitory concentrations of the scavenger in question. As shown in Table 7, these drugs have no effect on tumor lysis when added to cell mixtures that have successfully completed the binding step. As a positive control for suppression, we added catalase (500 U/mL) to cell mixtures that had completed the binding step in the calcium pulse technique and detected a decrease in killing from 55% to 21%.

Effects of myeloperoxidase inhibitors. To assess whether H_2O_2 induced tumor lysis by first interacting with myeloperoxidase and halide ions, several peroxidase inhibitors were added to the cytotoxicity assays. Aminotriazole, methimazole, cyanide, or azide had no effect on percentage of specific lysis, percentage of conjugation, or percentage of killing in the SCCA (Table 8). Because azide and cyanide prevent oxidative phosphorylation and might inhibit any tumor cell catalase present, they might also increase the sensitivity of targets to lysis, which could counteract any inhibitory effect on production of a cytotoxin by PMNs. Therefore, we performed experiments in which PMNs as well as targets were pretreated with cyanide (pH 7.4) and then washed extensively before they were mixed in the conjugation step. As shown in Table 8, pretreatment had no effect on PMNs but increased the susceptibility of targets to PMN-mediated lysis. These data support the notion that the

activity of myeloperoxidase is not required for effective tumor lysis.

Augmentation of tumor lysis by addition of PMA. As shown in Tables 1 through 5, significant numbers of conjugated tumor targets always remain viable during the incubation. Some conjugated targets may have escaped lysis because their bound PMNs produced insufficient levels of ROIs. To gain support for this hypothesis, we stained PMN-tumor cell mixtures with NBT to identify PMNs actively producing ROIs. We then attempted to correlate NBT positivity with tumor cell killing. The percentage of unbound PMNs elicited by IP injection of *C parvum* that stained positively with NBT ranged from 24 to 58, with a mean of 33% (Table 9). When SOD (200 U/mL) was present during preparation of PMNs and subsequent staining, NBT positivity was markedly reduced from 33% to 4% (Table 9). Peritoneal PMNs positively stained by NBT demonstrated coarse dark granules of formazan usually present asymetrically to one side of the cell. In contrast, MOT tumor targets were never stained with NBT.

Conjugates with dead tumor targets contained PMNs that were almost always NBT positive (Table 9). In contrast, conjugates with viable tumor cells contained PMNs that were positively stained for NBT only 29% of the time (Table 9). Thus, the ability of conjugating PMNs to kill their bound targets roughly correlates with their frequency of positive NBT staining.

These data suggested that bound tumor cells may evade cytolysis if their conjugating PMNs are insufficiently stimulated for an effective respiratory burst. To address this issue further, we incorporated increasing concentrations of PMA into the binding and killing phases of the SCCA. As shown in Table 10, the percentage of PMNs that conjugated targets was comparable between concentrations of PMA of 10^{-9} to 10^{-5} mol/L. However, the percentage of killing was related to the amount of PMA incorporated into the assay. Although killing could not be evaluated at 10^{-5} mol/L because of increased background toxicity on targets from the PMA, killing clearly peaked at 10^{-7} and 10^{-6} mol/L concentrations. These concentrations of PMA resulted in the greatest

augmentation of hydrogen peroxide production when added to *C parvum*-elicited PMNs (data not shown). These data indicate that a significant number of viable conjugated tumor cells can be lysed if their bound PMNs can be further stimulated to produce greater quantities of ROIs. However, 17% of bound tumor cells were still viable even with maximal PMA stimulation. As shown in Fig 1, this optimal concentration of PMA (10^{-7} mol/L) markedly increased the percentage of NBT positivity of free and conjugating PMNs. Specifically, 93% of conjugates with viable tumor cells contained NBT + PMNs, supporting the hypothesis that they were stimulated effectively by PMA but were still unable to cause lysis.

DISCUSSION

The ability of freshly obtained peritoneal inflammatory PMNs to lyse tumor targets spontaneously is novel because peripheral blood PMNs require prior in vitro activation to achieve lysis.[1-5] This paradox emphasizes the different functional capacities of PMNs obtained from different sites. Our results indicate that spontaneous tumor lysis was mediated by ROIs. Because in vitro-activated PB PMNs also induce cytolysis by production of ROIs,[1-5] the data suggest that the process of inflammation activates PMNs in vivo for an enhanced tumor-lysing oxidative burst.

SOD and catalase inhibited tumor cytolysis in a concentration-dependent fashion whereas heat-inactivated enzymes had no effect. In addition, suppression of lysis was greater when both inhibitory enzymes were used together, suggesting that hydroxyl radicals, formed by a reaction between superoxide and H_2O_2, were the lytic molecules. However, several hydroxyl radical scavengers, used in a wide range of concentrations, had no effect on postbinding lytic events. Sole use of a CRA would have led us to conclude erroneously that several scavengers could inhibit lysis. The SCCA demonstrated that these drugs had an inhibitory effect solely on tumor cell binding. The scavengers had no effect when they were added after binding had been completed. Nathan et al[17] also detected an inhibition of tumor cell binding to cytotoxic effectors caused by scavengers of hydroxyl radicals. These effects on binding are potential pitfalls in the interpretation of CRAs performed in the presence of these agents.

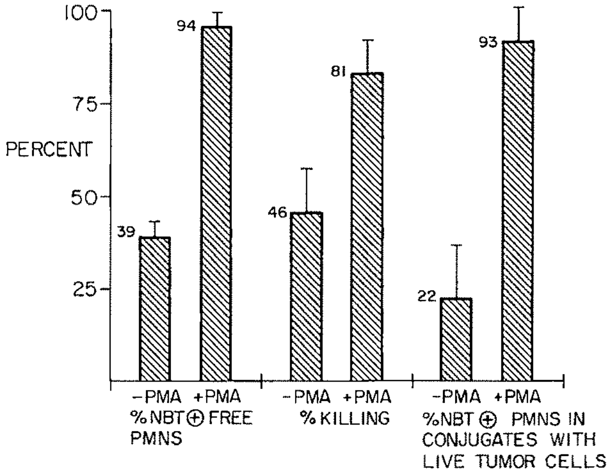

Fig 1. SCCA performed in the presence or absence of 10^{-7} mol/L of phorbol myristate acetate (PMA). Percentage of nitro blue tetrazolium (%NBT) positivity of free *C parvum*-elicited neutrophils (PMNs) was assessed on smears of peritoneal exudate cells (PECs) alone (no tumor targets), using triplicate slides per experiment. Data are presented as %NBT, mean ± SE of five separate experiments. Percentage of killing was determined with *C parvum*-elicited PMNs and murine ovarian teratocarcinoma (MOT) cells, effector–target ratio (E–T) 1:5, and is presented as percentage of killing (of bound tumor cells), mean ± SE of five separate experiments. Fifty-one conjugates with viable tumor cells were examined in the presence of PMA, and 82 conjugates were examined in the absence of PMA. Numbers next to bars are means.

It is possible that the scavengers tested could not gain access to the critical area of contact between PMN and tumor cell and therefore had no effect on postbinding lytic events. This may be a particular problem when the scavenger is added in the calcium pulse technique, ie, after binding is successfully completed. However, this is unlikely since protection against lysis was achieved by adding a large protein molecule such as catalase after binding was successfully completed.

A reaction between H_2O_2 and myeloperoxidase is not required for lytic effects to occur. Agents that inactivate myeloperoxidase had no effect on tumor lysis. Because azide and cyanide may affect targets by inactivating catalase and/or preventing oxidative phosphorylation, we pretreated PMNs and targets separately before initiating the cytotoxicity assay. Pretreatment of PMNs had no effect, but pretreatment of targets resulted in a modest increase in tumor cytolysis. Whether these latter effects are due to an inactivation of tumor cell catalase is unknown. However, it is clear that myeloperoxidase is not required for PMN-mediated lytic effects.

The lack of requirement for myeloperoxidase (MPO) is inconsistent with several previously reported studies.[1,2,12] However, studies by English and Lukens[4] and Nathan et al[18] demonstrated that MPO was not required for effective oxygen-mediated PMN lysis. One possible reason for these discrepancies is the different targets used in these studies. In experiments with the tumor target used in this study (MOT cells), the presence of halide and myeloperoxidase did not enhance lysis achieved by reagent grade H_2O_2 (unpublished observations).

The role of superoxide in PMN tumor cytotoxicity is not well established. Although human PMNs stimulated by lectins[19] or PMA[20,21] lyse erythrocytes through generation of superoxide, the only report to implicate superoxide in tumor cell killing is that of Mavier and Edgington,[22] who used PMN-stimulated peripheral blood monocytes as effectors. Although their SOD-induced protection from lysis was very modest, there appeared to be a synergistic cytotoxic interaction between superoxide and H_2O_2 (without evidence of a role for hydroxyl radicals), which is similar to results described here. Lysis of autologous erythrocytes by PMA-stimulated human PMNs also depends on the generation of superoxide and H_2O_2.[20] However, in this latter study, complete protection was afforded by either catalase or SOD (and not by hydroxyl radical scavengers), which implied an absolute requirement for simultaneous exposure to both oxygen metabolites.

The MOT tumor may be particularly sensitive to the lytic effects of superoxide as compared with previously studied targets. Further evidence of this sensitivity comes from preliminary experiments in which PMA stimulation of MOT-lysis by PMNs was significantly (but not completely) inhibited when SOD was present. In addition, PMA-stimulated lysis occurred equally under calcium-free conditions, thus correlating with the ability of PMA to stimulate superoxide release in the absence of calcium.

The additive effects of superoxide and H_2O_2 in the current study may be explained by a varying susceptibility to toxic oxygen molecules among the cells within our tumor population. Targets may be qualitatively heterogeneous, some primarily susceptible to superoxide-mediated damage and others susceptible only to H_2O_2. Thus, when catalase is added, H_2O_2-sensitive targets escape lysis; when SOD is added, superoxide-sensitive targets escape lysis. Alternatively, lysis may occur when a threshold of membrane damage is achieved by the additive effects of superoxide and H_2O_2. Tumor targets may then be quantitatively heterogenous in their individual threshold levels, susceptible targets being lysed by either H_2O_2 or superoxide alone and more resistant targets requiring the simultaneous presence of both metabolites for their effective lysis. Whichever theory is accurate, it is clear that there is variability among the targets in their susceptibility to lysis.

The activation of inflammatory PMNs in vivo that allows the production of ROIs in sufficient quantities for tumor lysis may be due to one or more of several stimuli. These cells have been exposed to chemotactic molecules and complement-opsonized bacteria during their egress into the peritoneal cavity and both are potent stimulators of the PMN respiratory burst.[23-25] It is also possible that these stimuli interact for an additive or synergistic release of oxygen metabolites. Pretreatment of leukocytes with chemotactic peptides[4,9] or opsonized zymosan[26] primes them for an increased respiratory burst following subsequent activation. It is quite possible, therefore, that in vivo exposures to chemoattractants and/or opsonized *Corynebacteria* effectively prime PMNs for a rapid and heightened production of superoxide and H_2O_2 when subsequent triggering occurs.

The presence of extracellular magnesium was necessary and sufficient for effective binding to tumor targets. These results are similar to those obtained when tumor cytotoxicity is mediated by sensitized T lymphocytes[27] or natural killer lymphocytes.[15] In contrast, only calcium is required for effective binding of antitumor macrophages to tumor targets.[28]

In contrast to binding, calcium was required for postbinding lytic events. Because these events involve the respiratory burst, calcium may be required for successful activation of PMN oxidative metabolism following binding to tumor cells. Calcium is needed for stimulation of the respiratory burst by many,[23,25,29-31] but not all[25] types of activators.

Magnesium may also be required for respiratory burst activation in some instances. Magnesium decreased the calcium requirements for superoxide release by digitonin-stimulated guinea pig PMNs.[29] An effective respiratory burst stimulated by serum-opsonized or C'3-opsonized zymosan also required the presence of magnesium as well as calcium.[25] In similar fashion, magnesium may be needed in addition to calcium for stimulation of tumoricidal PMNs. However, an alternative hypothesis is suggested by the strict requirement for magnesium in tumor cell binding. It is possible that when conjugates are resuspended in EDTA and agarose (Table 4), binding to tumor cells becomes sufficiently dissociated (even though this is not apparent microscopically) that effector cell stimulation does not occur. Thus, if only calcium is added back, PMNs are not sufficiently triggered by tumor cell contact to initiate the respiratory burst; if only magnesium is added back, membrane contact is sufficient but stimulation cannot proceed without extracellular calcium.

Most PMNs bound to viable tumor cells are NBT positive. Furthermore, the percentage of lysis could be significantly increased by incorporation of an optimal concentration PMA in the assay. Thus, a significant number of conjugating PMNs had not been activated for sufficient production of

Table 10. Enhancement of Tumor Lysis by Incorporation of PMA Into SCCA

oxygen metabolites necessary to effect tumor lysis; however, if further stimulated by PMA, they were capable of tumor cytotoxicity. It is unclear whether this is a random phenomenon or whether it represents true PMN heterogeneity, with specific subsets of cells being adequately stimulated for effective release of metabolites after tumor cell binding and other subsets requiring additional exogenous stimuli. The data in Table 10 and Fig 1 also indicate that some tumor cell resistance, at least in relative terms, exists in a subset of our targets. Even with optimal PMA stimulation, ~20% of bound tumor targets were still viable. Furthermore, most PMNs bound to these viable targets were stained positively with NBT, indicating that their production of reduced oxygen moieties had been significantly enhanced by PMA. Whether resistance is due to tumor cell catalase, as suggested by the data in Table 8, or to the operation of other biochemical pathways, is currently under investigation.

Prognostically Significant Classification of Immune Changes in AIDS With Kaposi's Sarcoma

By Jeremy Taylor, Rahmat Afrasiabi, John L. Fahey, Elizabeth Korns, Michael Weaver, and Ronald Mitsuyasu

Sixteen immunological parameters were assessed quantitatively for their value in providing an immunologically-based and prognostically significant classification of the immune alteration in 97 patients with AIDS and Kaposi's sarcoma (AIDS-KS). The dimensions of reductions in the T4 (T helper-inducer cells) subpopulation of lymphoid cells in the T4–T8 ratio were found to correlate most closely with prognosis. Most other immunological changes did not relate to clinical course. T4 lymphocyte levels $>300/\mu L$ and a T4–T8 ratio >0.5 indicated a relatively good prognosis, eg, 85% to 95% survival at 12 months. T4 levels $<100/\mu L$ and/or a T4–T8 ratio <0.2 had a very poor prognosis, eg, $<25\%$ survival at 12 months. Intermediate T4 levels and T4–T8 ratios had intermediate prognosis. These immunological findings were found to have independent prognostic value for survival when compared with disease classifications based on tumor stage (I through IV) or on clinical status A (without) or B (with fever, night sweats, or weight loss). Reduced proliferative capacity, increased OKT10 antigen expression, elevated levels of serum IgA, and immune complexes also correlated with prognosis. Elevated levels of serum IgG, cellular HLA-DR expression, and skin test anergy occurred frequently in AIDS-KS but did not have prognostic significance. Variations in level of total lymphocyte, T8 (T suppressor/cytotoxic) cell, gamma FcR receptor-positive cell number, NK activity, or level of serum IgM were less common in AIDS-KS and did not correlate with prognosis.

AIDS-ASSOCIATED Kaposi's sarcoma (AIDS-KS), in contrast to classical Kaposi's sarcoma, has an aggressive behavior.[1-4] Half of the patients have lymph node or gastrointestinal tract involvement at the time of diagnosis, and the disease generally has a progressive worsening clinical course over a period of months. AIDS-associated, epidemic, KS is associated characteristically with a profound suppression of cell-mediated immunity that is manifest as an absolute reduction in T4 (T helper/inducer) lymphocytes in the peripheral blood, resulting in an inversion of the T4–T8 lymphocyte subset ratio, reduced proliferative response to mitogens and alloantigens, and skin anergy to a variety of skin-test antigens.[3-6]

Because immunodeficiency is an essential element in the development of AIDS-KS and because patients with AIDS-KS differ in their course of disease, we attempted to determine which immune system changes, and which levels of change, were most relevant to prognosis. Ninety-seven patients with proven epidemic KS who were initially seen between January 1982 and February 1984 in the Kaposi's Sarcoma Clinic at UCLA Medical Center, were evaluated immunologically. Testing was performed on cellular and humoral immune parameters on presentation and at three-month intervals.

The relationship between immunologic parameters and clinical status (tumor stage, clinical subtypes A and B, and presence or absence of opportunistic infection) at the time of presentation and during the course of the disease was assessed. The prognostic value of the immunologic parameters at presentation on the course of the disease (survival and occurrence of opportunistic infection) was determined.

MATERIALS AND METHODS

Patients The study group consisted of 97 consecutive patients with biopsy-proven epidemic KS seen at the UCLA Kaposi's Sarcoma Clinic between January 1982 and February 1984 whose clinical and immunological status could be clearly determined Sixteen patients were excluded from the study because of inadequate histologic documentation of KS or because of incomplete clinical information Three patients with proven KS were excluded because their immunological status was within normal limits and because they showed no antibodies to HTLV-III. This group will be reported separately. All of the remaining patients from whom serum was available were found to have antibodies to HTLV-III virus. All patients were male homosexuals whose median age was 36 years with a range of 27 to 64 years There were no Haitians, Africans, or blood transfusion recipients among these patients. Patients were followed after their initial visit with clinical and immunological assessment at three-month intervals whenever possible.

In April 1985, 37 patients were still alive, 55 patients had died, and 5 were lost to follow-up. By June 1984, 56 patients had received treatment with α-interferon, 36 had received chemotherapy, and 3 were bone marrow transplant recipients, with many patients receiving more than one form of treatment; 25 patients had received no therapy. The results of these therapeutic trials have been reported[7-9] and are not considered in the scope of this study.

Fifteen patients had developed an opportunistic infection prior to, or at the time of initial presentation with KS (eg, *Pneumocystis carinii* pneumonia, *Candida* esophagitis, or *Toxoplasma gondii* encephalitis). Three patients had a history of lymphadenopathy prior to the diagnosis of KS. One patient had B cell non-Hodgkin's lymphoma diagnosed at the same time as KS.

The tumor stage (I through IV) and clinical subtypes A and B were established for each patient by a modification[4] of the criteria of Kriegel et al[10] on each date of immunological testing Tumor Stage I had limited cutaneous (one anatomic area) involvement and less than five cutaneous lesions; Stage II had disseminated cutaneous locations (more than one anatomic area) and more than five cutaneous lesions; Stage III had visceral involvement (gastrointestinal, lymph node, etc.); and Stage IV had both cutaneous and visceral

involvement. Clinical subtypes were either. (A) asymptomatic; or (B) exhibiting fever of >100 °F, lasting more then two weeks and unrelated to an identifiable source of infection; night sweats; or weight loss of ≥10% of body weight

If no immunological testing had been done over an interval of more than three months but the patient had been seen clinically during that period, tumor stage and clinical subtypes were still noted Follow-up of patients who had left the Los Angeles area was accomplished by telephone interview whenever feasible. The median time of follow-up was 12 months, with a range of 1 to 33 months

Immunological testing Total T4 cell number, total T8 cell number, T4–T8 ratio, and HLA DR and OKT10 antigen expression were performed on peripheral blood of all patients at the time of their routine clinical assessments approximately every three months. Tests for phytohemagglutinin (PHA) proliferative response. natural killer (NK) activity, and FcR cell tests were usually done at initial presentation and then periodically on most patients Skin testing was conducted on 51 patients at their initial visit only. The serum immunoglobulins IgG, IgA, and IgM, and immune complexes were measured at the initial clinical evaluation and were not generally repeated

Peripheral blood mononuclear cells (PBMCs) were obtained as either heparinized (functional assays) or EDTA-treated (phenotype assays) venous blood. Total lymphocyte count and T cell subsets determination were accomplished by surface phenotype analysis using fluorescent monoclonal anti-T cell antibodies [6]

In brief, 50 μL of whole blood was treated with a RBC lysing reagent. The residual PBMCs were studied with stained fluorescein-conjugated monoclonal antibodies. T cell subpopulations were determined using an Ortho Spectrum III fluorescent-cell analyzer (Raritan, NJ) The monoclonal antibodies used and the respective mononuclear cell subpopulations are as follows· Leu4 (pan-T cell marker); Leu3a (T helper/inducer, T4); Leu2a (T suppressor/cytotoxic, T8) (Becton Dickenson, Mountain View, Calif); and HLA DR and OKT10 (Ortho) as markers of early T cell differentiation antigens. Total numbers of these subpopulations were derived from measurements of total WBC count and differential count (for lymphocytes) by standard methods. The NK activity was assayed using radiolabeled (^{51}Cr) K562 target cells and lymphocyte effector cells at an effector–target cell (ET) ratio of 10:1 as described by Spina et al.[11]

Mitogen-induced proliferation to PHA was tested in a microassay as previously described.[12] PBMCs were cultured with a 1:100 dilution of PHA (Burroughs Wellcome) for 48 hours at 37 °C. Tritiated thymidine was added to the cultures, and cells were harvested 24 hours later and counted on a Beckman scintillation counter. Data are expressed as cpm × 10^{-3}. Skin tests to recall antigens including mumps, intermediate-strength purified protein derivative of tuberculin (PPD), and *Candida* were performed; induration of ≥5 mm after 48 hours was considered positive

Total serum immunoglobulins including IgG, IgA, and IgM were measured in the clinical chemistry laboratory at UCLA Medical Center by the laser nephelometry method (PDQ Laser Nephelometry, Hyland Laboratory, Deerfield, Ill). Circulating immunocomplexes (CIC) were measured using polyethelene glycol precipitation techniques [13]

Statistical methods. Wilcoxon rank-sum tests were used for comparisons of groups and subpopulations. Survival analyses were performed using Kaplan-Meier plots[14] and Cox proportional hazard models [15] Because levels of many immunologic parameters are being simultaneously compared, it is necessary to correct for multiple comparisons This is done using the conservative Bonferroni approach, in which the Bonferroni significance level is .05 divided by the number of comparisons. In Tables 1 through 3, *P* values of <.05 are marked with a single asterisk (*); this indicates a probable relationship, but should be viewed with some skepticism. Parameters marked with double asterisks (**) indicate *P* values that are less than the Bonferroni significance level; these should be regarded as strongly indicative of a relationship

RESULTS

The immunologic changes observed at presentation in the 97 patients with AIDS-KS showed increases of some param-

Table 1. Immunological Parameters by Tumor Stage at Initial Presentation

Immune Parameter*	Tumor Stage I n = 23	 II n = 40	 III n = 10	 IV n = 24

†Numbers in the table are the P values of univariate Cox proportional hazards analysis.

‡P value <.05

§P value less than Bonferroni significance level

eters and decreases in others. In >50% of patients, decreased values (below the 5th percentile) were noted in total T4 numbers and T4–T8 ratio; increased values (above the 95th percentile) were seen in percentages of OKT10 and HLA DR cells, serum IgG, and immune complexes. In 30% to 50% of patients, decreased values of WBC, total lymphocytes, total T cells, and PHA proliferative response were observed, as were increased levels of serum IgA. In 10% to 30% of patients, decreased NK activity was documented, as was increased total T8 and serum IgM. Decreased FcR$^+$ cells were seen in <10% of patients.

Survival analysis. The important prognostic immunologic parameters at presentation (and their statistical significance) were identified as· decreased T4–T8 ratio ($P < 10^{-4}$), decreased total T4 cells ($P < 10^{-4}$), decreased PHA proliferative response ($P < 10^{-4}$), immune complexes ($P < 10^{-2}$), increased OKT10 antigen expression ($P < 10^{-4}$), and increased serum IgA level ($P < 10^{-2}$). No statistically significant correlations with survival were found for WBC count, total lymphocytes, total T cells, total T8 cells, HLA DR antigen expression, FcR$^+$ cells, NK activity, serum IgG, or IgM

The Kaplan-Meier survival curves for T4–T8 ratio, total T4 cell numbers, PHA proliferative response, and total T8 cells are shown in Fig 1. The T8 level does not correlate with survival, although the other immune parameters do

A comparison of the immunologic parameter at initial examination between those who received no treatment and those who received some form of therapy showed no significant differences. Therefore, even if the treatments prolonged life, the above survival analysis is still valid.

Relationship of immune parameters to tumor stage. The immunologic status of the patients at presentation with KS tumor stages I, II, III, and IV were compared (Table 1). Differences in the mean values of total T4 cells, T4–T8 ratio, and T10 expression are seen between the four subpopulations. These findings were confirmed on repeat analysis at the last time a blood specimen was tested for each patient. The values in Table 1 show that the order of the tumor stages that gives the closest correspondence to the seriousness of the immunologic abnormality with increasing order of severity is (I and III), II, and IV.

The importance of the immunologic parameters to patient survival was assessed by univariate proportional hazards survival analyses on two patient subpopulations. those presenting with Stage I and III tumors and those presenting with Stage II and IV (Table 2). The immunologic parameters, particularly T4–T8 ratio, total T4 cells, and PHA proliferative response have important prognostic value within the subpopulations. These immunologic measurements clearly provide independent prognostic information

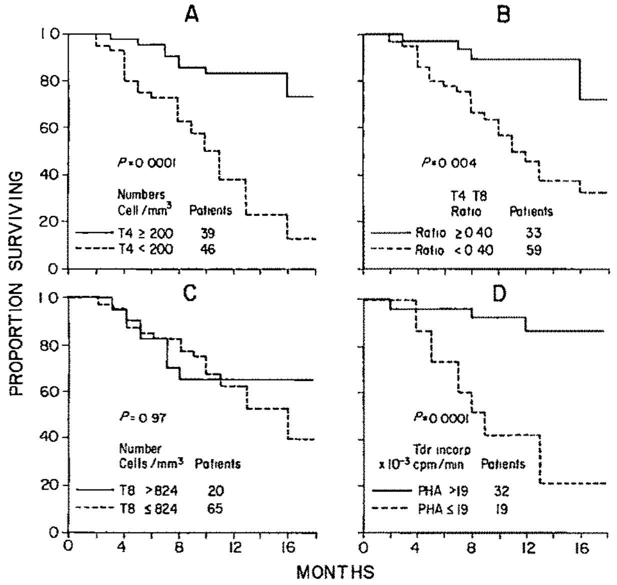

Fig 1. Relationship of survival of AIDS Kaposi's sarcoma patients to immunological parameters at the time of initial presentation: (A) T4 (CD4) cell numbers; (B) T4–T8 (CD4–CD8) ratio; (C) T8 (CD8) cell numbers; (D) proliferative response to phytohemagglutinin.

that is distinct from prognostic information based on tumor stage.

Relationship of immune parameters to clinical level. Clincal subtypes A and B differed in initial total T4 cells, T4–T8 ratio, and PHA proliferative response (all decreased), and in T10 antigen expression and serum immune complexes (both increased) (Table 3). No significant differences existed for total lymphocytes, total T cells, total T8 cells, HLA DR expression, or serum immunoglobulins. When the analysis was performed for the last time and a blood specimen was taken from the patient, the same differences between A and B clinical subtypes were seen.

The relationships of the immunologic parameters to patient survival within each clinical group were analyzed separately and found to add significant information (Table 2). Total T4 cells, T4–T8 ratio, T10 expression, and PHA proliferative response provide prognostic information for patients within clinical subtype A, indicating that an immunologic evaluation of clinical subtype A patients is useful Survival in patients with clinical subtype B, however, did not correlate with immunologic parameters. When both clinical subtype and tumor stage were combined to determine prognosis, a multivariate survival analysis revealed that total T4, T4–T8 ratio, and PHA proliferative response each gave additional survival information (data not shown) at $P <$ .002.

Skin tests were performed in 51 patients; 12 were positive responders. In tumor Stages I and III, there were 6 responders in 12 patients; in Stages II and IV there were only 6 responders in 39 patients tested. In clinical subtype classifications A and B there were 9 in 31 and 3 in 20 responders, respectively. Skin test anergy was found not to be of prognostic significance for survival ($P = .27$) The positive and negative responders did not show statistically significant differences in any of the immunological parameters considered.

Opportunistic infection. Fifteen patients had a prior or concurrent opportunistic infection (OI) at the time of diagnosis with KS. We investigated the immunologic characteristics of this group and the relationship between the immunologic parameters and the development of OI. The OI group was found to have lower T4–T8 ratios ($P < .01$), total T4 cells ($P < .01$), WBCs ($P < .01$), and total lymphocytes ($P < .05$). There were no statistically significant differences in total T8 cells, total T cells, T10 and HLA-DR antigens, PHA proliferative response, FcR cell number, NK activity, serum IgG, IgA, and IgM, or immune complexes between those with and without prior OI. The findings with respect to lower T4–T8 ratio and total T4 cell number agree with the observation that OI generally occurs with more serious immunologic impairment than does KS alone.[16]

The relationships between the immunologic parameters at initial examination with the time to future occurrence of opportunistic infections were also investigated. A univariate analysis on the time to occurrence of OI revealed that patients with lower T4–T8 ratios, total T4 cells, and PHA proliferation tended to get OIs sooner than did patients with higher ratios ($P < 10^{-4}$ for each parameter). Similarly, parameters such as T10 antigen expression ($P < 10^{-3}$), serum immune complexes ($P < .05$), and IgA ($P < .05$) related (although less well) to development of subsequent OIs. Other parameters were found not to be significant.

The above analysis shows that the occurrence of OIs is strongly related to the immunologic condition of the patient. It also indicates that immunologic abnormalities precede the development of OIs; they are not the result of OIs. The immunologic variables which are significant to OI occurrence also relate to survival; of the patients who died nearly all died as a result of OIs rather than from complications related solely to KS.

Critical immunological values. The findings noted above give strong evidence that several immunologic parameters provide valuable information in predicting the course of patients' disease. Thus, an immunologic staging of KS

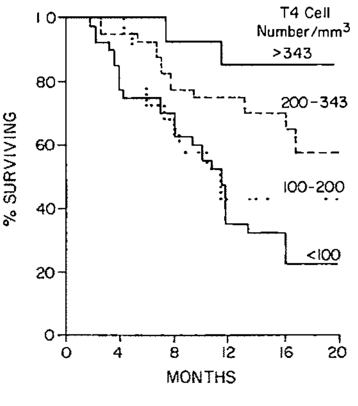

Fig 2. Relationship of various levels of T4 (CD4) cell numbers to survival in AIDS-Kaposi's sarcoma patients (Kaplan-Meier graph).

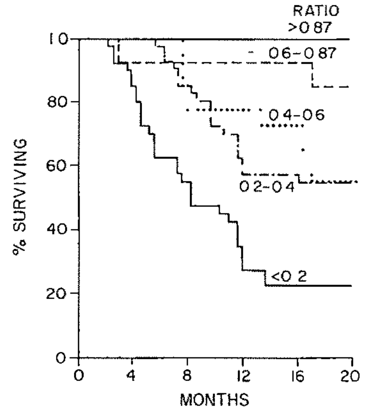

Fig 3. Relationship of various levels of T4–T8 (CD4–CD8) ratio to survival in AIDS-Kaposi's sarcoma patients (Kaplan-Meier graph).

patients should be valuable. Figures 2 and 3 show the strong relationship between T4 cell numbers and T4–T8 ratio and survival; they also show that prognosis changes rapidly as the immunologic values decrease.

By comparing survival curves for various levels of total T4 cell numbers and of T4–T8 ratio at initial examination, values indicating good, intermediate, and poor prognosis were obtained (Table 4). Eighty-five percent of patients with T4 values >300/μL and 95% of patients with T4–T8 ratio >0.5 survived 12 months, respectively. In contrast, only 35% of patients with T4 levels <100/μL and 25% of patients with T4–T8 ratio <0.2 survived 12 months. In the intermediate range of immunologic values, the prognosis changes rapidly as the values decrease. Two critical values were chosen as compromise numbers. One value would have been simpler; however, it would not have represented the large differences in survival rates accurately.

DISCUSSION

Immunologic changes relevant to prognosis are restricted to only a few parameters. Decreased T4 cell numbers and T4–T8 ratio are shown to be the most significant immunological changes in relation to prognosis and to OI development. The T4 lymphoid cell subpopulation and its reduction appears to be the central feature of AIDS. The evidence that HTLV-III is preferentially cytopathic for T4 cells[17] indicates that direct damage by the virus to T4 cells undermines the immune system; the present data point to T4 cell reduction as the key factor leading to the life-threatening complications which make AIDS such a serious disease.

Most patients with AIDS-KS are reported to have antibodies to HTLV-III[18] which is consistent with the view that HTLV-III is the etiologic agent for AIDS. Currently, available data indicate that the presence of antibodies to HTLV-III is not the key prognostic factor in AIDS-KS. Rather, the cellular immune parameters (represented in the range of T4 cell levels and T4–T8 ratios found in AIDS-KS) reflect the central pathogenic effects of HTLV-III infection and correlate with prognosis.

Immune deficiency in AIDS is manifested primarily by a deficiency of the T4 (T helper) subpopulation of lymphoid cells. Direct measurement of T4 cell numbers may provide the best prediction of prognosis. The major limitation in T4 cell quantitation is the dependence on WBC counts and differential leukocyte determinations to provide an absolute number of lymphocytes per microliter. This essential step in quantitation has far more variabilities than does the actual measurement of the percentage of T4 antigen-bearing lymphoid cells (the CD4 and T4 subpopulation)

Table 4. Critical Values of T4–T8 Ratio and T4 Cell Numbers to Prognosis

	Immunologically Defined Prognosis		
	Better	Intermediate	Poor
T4–T8 ratio	>0 5	0 5–0 2	<0.2
Surviving 12 months	>95%	(Intermediate)	25%
T4 cell numbers/μL	>300	300–100	<100
Surviving 12 months	85%	(Intermediate)	35%

Measurement of T4–T8 ratio avoids the problems associated with quantitation of lymphocytes by means of WBC and differential counts since it can be determined directly from measurements of the percentages of cells with T4 and with T8 antigens. This measurement, however, is subject to biologic variability in the level of T8 cells. The T8 cells can be changed by infections[19] and, probably, by various circumstances that have no relation to prognosis in AIDS. Our data confirm that T8 cell levels do not relate to prognosis in AIDS-KS patients. However, variation in T8 levels affects the T4–T8 ratio and reduces the precision of applying ratio measurements to AIDS prognosis.

Despite the limitations on T4 cell enumeration and T4–T8 ratio measurements, they correlate well (and better than any other parameter) with prognosis. Both measurements are recommended and can be easily made simultaneously. A repetition of the tests will also increase the value of the measurements.

These quantitative extrapolations are based on the premise documented here—that susceptibility, or lack of susceptibility, to infection is related to the quantity of T4 cells. Another immune parameter evaluated in conjunction with T4 cell numbers (or T4–T8 ratio) may improve prognostic capacity further. Such an association may also point to functional cooperation within the immune system and provide clues for better understanding of the immune system's protective functions and its potential for failure.

Measurements of T4 levels and/or T4–T8 ratio were found to have a significance that was independent of clinical status or KS tumor stage. In patients with AIDS-related complex and oral candidiasis,[20] the presence of T4–T8 ratio <0.51 has been reported to be associated with a high likelihood of developing advanced AIDS. A T4–T8 ratio >0.6 indicated a much better prognosis in these patients.

The T4 lymphoid subpopulation numbers appear normally to provide a considerable margin of protection before OIs occur. Reduction in T4 cell levels to below normal range was characteristic of AIDS-KS but was not sufficient to establish prognosis. The 5th percentile value for a normal population is more than three times greater than the critical value seen for poor prognosis in this study. Estimates of protective margin will have to be refined when the subpopulation of the T4 lymphoid cells most relevant in protection against viral, fungal, protozoal, and other infections occurring in AIDS patients has been identified.

Classical KS occurs without evidence of immune deficiency.[1-2,21] Thus, resistance or susceptibility to KS relates with less exactness than do OIs to T4 cell levels. Perhaps circumstances of host resistance or other co-factors play large roles in the initiation and development of KS.

Increases of B cell activity such as the elevated serum IgG and IgA and immune complex levels, B cell numbers in lymphoid tissues,[22] and spontaneous Ig-secreting cells,[23] are seen in many phases of AIDS. These B cell changes contrast with the reductions seen in many T cell parameters. These differences emphasize the complexity of immune cell alterations in AIDS-KS. Some of the B cell changes may reflect a lack of the immune regulation normally provided by T cells. They may also reflect either direct or indirect stimulation of B cells by HTLV-III. The B cell changes, however, do not appear to be relevant to prognosis in AIDS-KS patients. The elevation of OKT10 and HLA-DR antigens may represent an overall activation or immaturity in the lymphoid cells in AIDS patients. This question is the focus of ongoing investigations.

Clearly, the major problem in AIDS-KS is the immune deficiency. KS regressed in several transplant patients receiving immunosuppressive drugs when the immunosuppression was ended.[24,25] Correction or prevention of the T4 lymphoid cell deficiency in epidemic KS will be of prime therapeutic importance.

Survival and Recovery of Human Platelets Stored for Five Days in a Non-Plasma Medium

By G.A. Adams, S.D. Swenson, and G. Rock

Human blood platelets were stored for five days as concentrates in 60 mL of: (a) plasma; (b) non-plasma medium with anticoagulant; and (c) non-plasma medium without anticoagulant. All preparations were equally functional when tested for platelet aggregation and release reaction in response to single agonist or synergistic pairs of agonists in vitro. Platelets stored in non-plasma medium with anticoagulant had lower kallikrein, fibrino(gen)peptide A, lactate, and β-thromboglobulin than did plasma controls after five days. In vivo recovery and survival of platelets stored in non-plasma medium with anticoagulant were 51.2% ± 4.3% and 8.7 ± 0.3 days, respectively, which were not statistically different from plasma controls of 39.2% ± 4.9% and 7.2 ± 0.8 days, respectively. It is concluded that platelets can be stored for five days in a non-plasma medium and still have good in vivo recoveries and survivals.

©1986 by Grune & Stratton, Inc.

BLOOD PLATELETS are routinely isolated from whole blood, concentrated, and stored in plasma for use in transfusion therapy.[1] Such platelet concentrates can be stored for five or even seven days and still be therapeutically effective in thrombocytopenic patients. Early attempts to store platelet concentrates in volumes of plasma below the normal 50 mL in polyvinylchloride bags led to a precipitous drop in pH that was associated with irreversible damage to platelets.[2-4] Thus, plasma has been considered essential for the storage of platelets for long periods. We have earlier reported on the good maintenance of in vitro platelet function when platelets were stored for three days in a modified Tyrode's buffer.[5] This report documents the storage of platelets in an infusable non-plasma medium that preserves their in vitro function for at least five days of storage, following which in vivo recovery and survival are normal.

MATERIALS AND METHODS

Materials. ^{14}C-Serotonin (5-hydroxytryptamine creatinine sulphate, Amersham Corporation, Oakville, Ontario) was diluted to 150 μmol/L in 2% ethanol in distilled water and frozen Bovine tendon collagen (SIGMA Chemical Company, St Louis) was prepared by the method of Cazenave et al[6] ADP (SIGMA) was dissolved in normal saline to 10^{-4} mol/L and frozen. The ionophore, A23187, (SIGMA) was dissolved in dimethylsulfoxide (DMSO) to 10^{-2} mol/L and then diluted to 5×10^{-5} mol/L in normal saline Epinephrine (Eastman-Kodak, Toronto) was prepared at 1.0 mmol/L in 0 15 mol/L NaCl and 1.0 mmol/L of tartaric acid, diluted to 5×10^{-4} mol/L with normal saline, and frozen Lyophilized sodium arachidonate (Bio Data Corporation, Hatboro, Pa) was reconstituted according to the company's instructions Non-plasma media were prepared by mixing concentrated sodium citrate (46 7% trisodium citrate, Haemonetics Corporation, Braintree, Mass), dextrose for injection (50%, sterile and nonpyrogenic), and Plasma-Lyte A (90 mmol/L NaCl, 23 mmol/L of sodium gluconate, 27 mmol/L of sodium acetate, 5 mmol/L of KCl, 3 mmol/L of $MgCl_2$, 294 mosm/L, pH 7.4, Travenol Canada Inc, Mississauga, Ontario). The standard non-plasma medium was composed of 59 mL of Plasma-Lyte, 0 5 mL of concentrated citrate and 0 5 mL of 50% dextrose and designated PCD One other non-plasma medium, PCD, was studied; it was free of citrate and designated PD Mixtures were made with the aid of (Millex-GS, Millipore Corp, Bedford, Mass) 0 22-μm filter units and medication injection sites

Paired studies, in vitro. Whole blood from nine normal healthy donors was collected into CPDA-1 anticoagulant. One tube was collected from each bag so that the platelets could be tested for biphasic response with epinephrine. Seven responsive units were chosen and centrifuged at 1,000 g for seven minutes in a Sorvall RC-3B at 22 °C The PRP was extracted into satellite bags and subsequently pooled and divided into six new transfer packs (Fenwal PL732, 300-mL capacity) to give 72×10^9 platelets per bag. All six units were centrifuged at 3,350 g for six minutes on the Beckman Model J-6M centrifuge, and most of the plasma was removed, leaving 7 to 9 mL The concentrated platelets were left to sit at room temperature undisturbed for one hour, after which plasma was added back to the controls and non-plasma media was added to the others. Final volumes of platelet concentrates were 60 mL. The platelet concentrates were stored at 22 °C on a vertically rotating shaker at 6 rpm (Helmer Labs Inc, St Paul) After five days, the platelets were tested for in vitro function.

Platelet function testing Platelet concentrates were diluted to 3×10^8 platelets per milliliter with either autologous plasma, non-plasma medium, or both, to standardize the aggregation conditions to three parts plasma and one part non-plasma medium After incubating with 1.0 μmol/L of ^{14}C-serotonin at 22 °C for one hour, imipramine to 2 μmol/L was added to prevent reuptake of serotonin, and platelet aggregation and the release reaction were measured Platelet stimuli were prepared at ten times final concentration and added to platelet suspensions singularly or in pairs. The following final concentrations of the aggregating agents were used epinephrine 5×10^{-5} mol/L, ADP 10^{-5} mol/L collagen 5.0 μg/mL, A23187 10^{-6} mol/L, and arachidonic acid 0.33 mg/mL. Aggregation was defined as the maximum change in transmittance after stimulation. Four minutes after stimulation, the samples were centrifuged at 15,000 g for one minute in an Eppendorf centrifuge [Brinkman Instruments (Canada), Rexdale, Ontario] to obtain supernatant samples The percentage of release of ^{14}C-serotonin was calculated as previously reported[7] Platelet and WBC counts were done on the Coulter Counter (Model ZBI, Coulter Electronics, Hialeah, Fla) Aggregations were performed on Payton aggregometers (Payton Instruments, Toronto), and radioactivity was measured using the Beckman LS7500 liquid scintillation system (LS7500, Beckman Instruments Inc, Irvine, Calif) To illustrate the results graphically, a "synograph" was constructed by plotting the level of aggregation or release response to the various stimuli on each spoke of a 16-spoke polar graph By joining the points, an image is generated that is easily remembered and that facilitates comparison between different platelet preparations and periods of storage. The upper right quad-

rant shows the results from single stimuli; the three other quadrants indicate the responses obtained with pairs of stimuli.

Analysis of media. The pH, pCO_2, and pO_2 of the platelet concentrates were measured with a Corning 165/2 blood gas analyzer (Corning Medical, Corning Glass Works, Medfield, Mass) at 37 °C. Glucose concentrations were determined using Fisher Diagnostics (Fair Lawn, NJ) Glucotall reagent. Lactate measurements were performed using the Boehringer-Mannheim (F.R.G.) lactate kit. Kallikrein was measured by the Diagnostica Stago (Asnieres, France) kit. β-Thromboglobulin was measured using the radioimmunoassay kit from Amersham and fibrino(gen)peptide A by the kit from Mallinckrodt (St Louis).

Autologous reinfusion studies. Autologous reinfusion studies were approved by the Medical Ethics Committee of the Ottawa General Hospital. A unit of whole blood was withdrawn from volunteers into a CPDA-1 triple pack using standard blood banking procedures. The platelets were concentrated, and as much plasma was removed as was possible. PCD was added to the platelet concentrate, which had rested undisturbed for one hour, to a final volume of 60 mL. A sample was removed for blood culture. The platelet concentrate was stored at 22 °C on a vertically rotating shaker at 6 rpm (Helmer Labs, Inc). After five days, the platelets were radiolabeled with ^{51}chromium according to recommended procedures.[8] The platelet concentrates were infused, and blood samples were collected for seven days. Platelet recovery was calculated using the average of the samples taken two and three hours after infusion; platelet survival was calculated using Murphy's multiple-hit program.

RESULTS

Two non-plasma media, PCD and PD, were used to support human platelets during storage for five days at 22 °C. The fibrino(gen)peptide A levels were greater in the PD medium with no anticoagulant than in the media, PCD, to which anticoagulant was added (Table 1). Platelet count, WBC count, pH, pCO_2, pO_2, glucose, lactate, and kallikrein were not significantly different for either non-plasma media. The plasma concentration of lactate (122 mg/dL) was twice as high as the PCD concentration of lactate (60 mg/dL). The dextrose levels were 434 mg/dL in the PCD as compared with the plasma levels of 373 mg/dL (Table 1). The kallikrein and β-thromboglobulin levels were also lower in the non-plasma medium than in the plasma after five days. Between the media and plasma, no other parameters were significantly different.

In vitro evaluation of these preparations demonstrated that platelets stored in PCD (Fig 1), PD (Fig 2), and plasma (Fig 3) had maintained their functions of aggregation and the release reaction to synergistic pairs of stimulants. Platelet responses to single stimulants were similar for PCD, PD, and plasma, but were less than the responses exhibited on the day of blood collection (data now shown). Statistical analysis of the synographs (Figs 1 through 3) were performed by calculating the paired difference for all the stimuli for both platelet responses. Platelets stored in PCD had better aggregation responses with a mean (SE) of 6% (1.3), n = 120, but had less average release of serotonin by 7.7% (1.4) compared with the plasma controls after five days of storage. Platelet concentrates stored in PD had an average 4.0% (1.0), n = 90, more aggregation and 1.8% (1.5) less release of serotonin than did plasma controls after five days of storage.

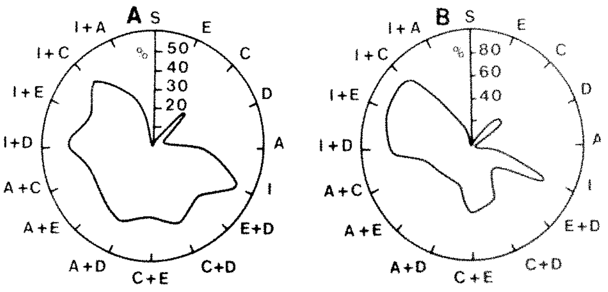

Fig 1. Synographs for platelets stored for five days in PCD (non-plasma medium). Platelet aggregation (left) and release of serotonin (right) induced by epinephrine (E), collagen (C), ADP (D), arachidonic acid (A), ionophore A23187 (I), and their binary combinations. Response is plotted as radial distance from the center of the synograph.

Autologous platelets stored for five days in the non-plasma medium and transfused into volunteers yielded excellent in vivo platelet recoveries of between 40% and 60% and mean platelet survivals of between 8.3 and 9.4 days (Table 2). The survival curves were all linear (Fig 4). The control values, reported in Table 2, were obtained with platelets stored in PL732 bags for five days as reported previously.[9] Blood cultures were negative on all preparations.

DISCUSSION

Plasma is generally not required by patients receiving platelet therapy and would be used more efficaciously if directed to fractionation. A preliminary report of the ability

of non-plasma media to support platelet storage was presented by us in 1982[5] and recently confirmed by another group.[10] This report documents the ability of a non-plasma medium to support platelets adequately during five days of storage. There are many possible advantages to storing platelets in a non-plasma medium. The more precise control of the environment during storage should lead to a more consistent product. This, in turn, should lower the number of units required per infusion and hence reduce demand. The removal of plasma should diminish the risk of transfusion of infectious agents, toxins, allergens, or drugs. Last, the recovery of addditional plasma for fractionation should help prevent the adoption of expensive alternate plasma procurement procedures.

The decreased levels of lactate in the non-plasma media may offer a clue as to how the media were able to maintain platelet function so well. It has been suggested that increased oxygen transfer through the PL732 bags promotes aerobic metabolism[3] and recent analyses have suggested that the rate of lactate production is five to eight times less in well-oxygenated conditions relative to anaerobic conditions.[11] It is unlikely that the non-plasma medium could have facilitated oxygen diffusion because the bag is the limiting resistance. However, the non-plasma medium was at atmospheric oxygen tension when it was added to the concentrated platelets. This is in contrast to the situation with plasma, which is at venous oxygen levels when collected and which takes hours to days to return to atmospheric tension during storage.[9] Therefore, it may be this rapid return to high oxygen concentration on addition of the non-plasma medium that maintains aerobic metabolism and reduces lactate production during storage.

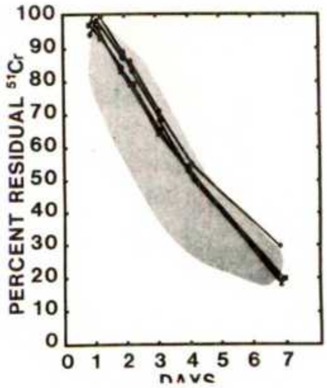

Fig 4. Platelet survival curves in four volunteers who received autologous platelets that were stored for five days in PCD (non-plasma medium). Shaded area is range of results from reinfusion of platelets stored in plasma under identical conditions.

The low levels of fibrino(gen)peptide A demonstrated that anticoagulant carried over with the residual plasma in the platelet concentrates with non-plasma medium was sufficient to guard against activation of coagulation during storage. Because there was still ~15% plasma in the platelet concentrates, this could have generated a maximum of 13,000 ng/mL (3.0 mg/mL of fibrinogen in plasma × 10,000/330,000 [mass ratio of fibrino(gen)peptide A to fibrinogen] × 15%), whereas only 3.4 to 4.4 ng/mL was detected. Therefore, although the non-plasma medium for the in vivo study (PCD) contained anticoagulant as a safety precaution, it may not have been necessary.

The decline during storage of platelet aggregation and release of dense granules in response to activation by single

Table 2. Survival and Recovery of Autologous Platelets Stored for Five Days in a Non-Plasma Medium, PCD, and Transfused Into Healthy Volunteers

		Platelet Survival (d)

Be	9.4	8.6	9.4	25	49.1
Mean (SE)	8.7(0.3)	8.1(0.2)	8.7(0.3)	25(0)	51.2(4.3)
Laboratory averages	7.2(0.8)		6.0(1.4)		39.2(4.9)

stimuli, but not pairs of stimuli, has been reported previously.[12] A similar pattern of dysfunction was observed in platelets after storage in the non-plasma media either with or without anticoagulant (Figs 1 through 3), implying that the acquired defects are not induced by plasma but are due to other factors, which could include contact with the plastic bag, leachables from the bags, or self-inflicted injury by the platelets themselves.

The in vivo recoveries of platelets that were stored in a non-plasma medium (PCD) were higher but not statistically different from those platelets that were stored in plasma, 51.2% *v* 39.2%, $P > .05$, respectively. The in vivo survivals were also higher but not statistically different (8.7 days *v* 6.0 days $P > .05$) for platelets stored in PCD when compared with storage in plasma. The linear nature of the survival curves (Fig 4) is indicative of the nonconsumptive removal of platelets by healthy individuals. The excellent in vivo recovery and survival of the platelets that were stored in the non-plasma medium encourages the clinical testing of these preparations in thrombocytopenic patients to demonstrate their therapeutic capacities. The similar levels of β-thromboglobulin in the plasma and non-plasma media suggest that the platelets have undergone identical degrees of activation during storage and should have equal hemostatic properties. This contention remains to be proven.

ACKNOWLEDGMENT

We would like to acknowledge the assistance of Rod Butt, McMaster University, Hamilton in analysis of the platelet survival and recovery data and of P. Tittley in performing the in vivo experiments.

Cellular *ras* Oncogene Expression and Cell Cycle Measured by Flow Cytometry in Hematopoietic Cell Lines

By Michael Andreeff, Dennis E. Slater, Jan Bressler, and Mark E. Furth

Human hematopoietic malignancies provide an excellent model for the study of the activity of cellular oncogenes in a context of known defects in cell proliferation and differentiation. A flow cytometric immunofluorescence assay was developed to quantitate the expression of the cellular *ras* oncogenes in relation to the cell cycle in individual leukemic cells. Specific binding of a monoclonal antibody to the 21-kd protein (p21*ras*) encoded by the Ha-*ras*, Ki-*ras*, and N-*ras* genes was measured by flow cytometry and confirmed by fluorescence microscopy. P21*ras* was detected in 416B, a murine hematopoietic precursor cell characterized by a high level of Ki-*ras* expression, and in the human leukemic cell lines P-12 and KG-1. The presence of p21*ras* in the cell lines was also shown by immunoprecipitation. Cellular DNA content was determined simultaneously to define cell cycle phases. There was an equal distribution of p21*ras* in G_1, S, and G_2M, with considerable heterogeneity of *ras* gene expression in the G_1 compartment. The assay allows oncogene expression to be studied in populations of intact single cells in which cell heterogeneity is maintained, requires very few cells per sample, and directly correlates oncogene expression to cell kinetic data.

DNA ISOLATED from a wide variety of malignant cells can induce cell transformation when transfected into cultured NIH 3T3 mouse fibroblasts. In 10% to 20% of human tumors,[1] the activated transforming genes are related to the oncogenes of the Harvey or Kirsten murine sarcoma viruses or to the N-*ras* gene originally described in the human SK-S-NH neuroblastoma cell line.[2] The N-*ras* gene is of particular interest since it has been found in human T and B cell leukemia cell lines, myeloid and Burkitt's lymphoma cell lines, and in primary AML.[3-7] All three cellular *ras* genes encode proteins weighing 21,000 daltons (p21*ras*)[8,9] whose biochemical activity is the binding of guanine nucleotides.[10] H-*ras* has also been shown to have GTPase activity.[11-14] P21*ras* is localized on the inner surface of the cell membrane.[15] Point mutations in the cellular *ras* genes involving amino acid substitutions at positions 12 or 13 or 59 through 63 of p21*ras* can result in oncogenic activation.[16-21] Cell transformation has also been associated with

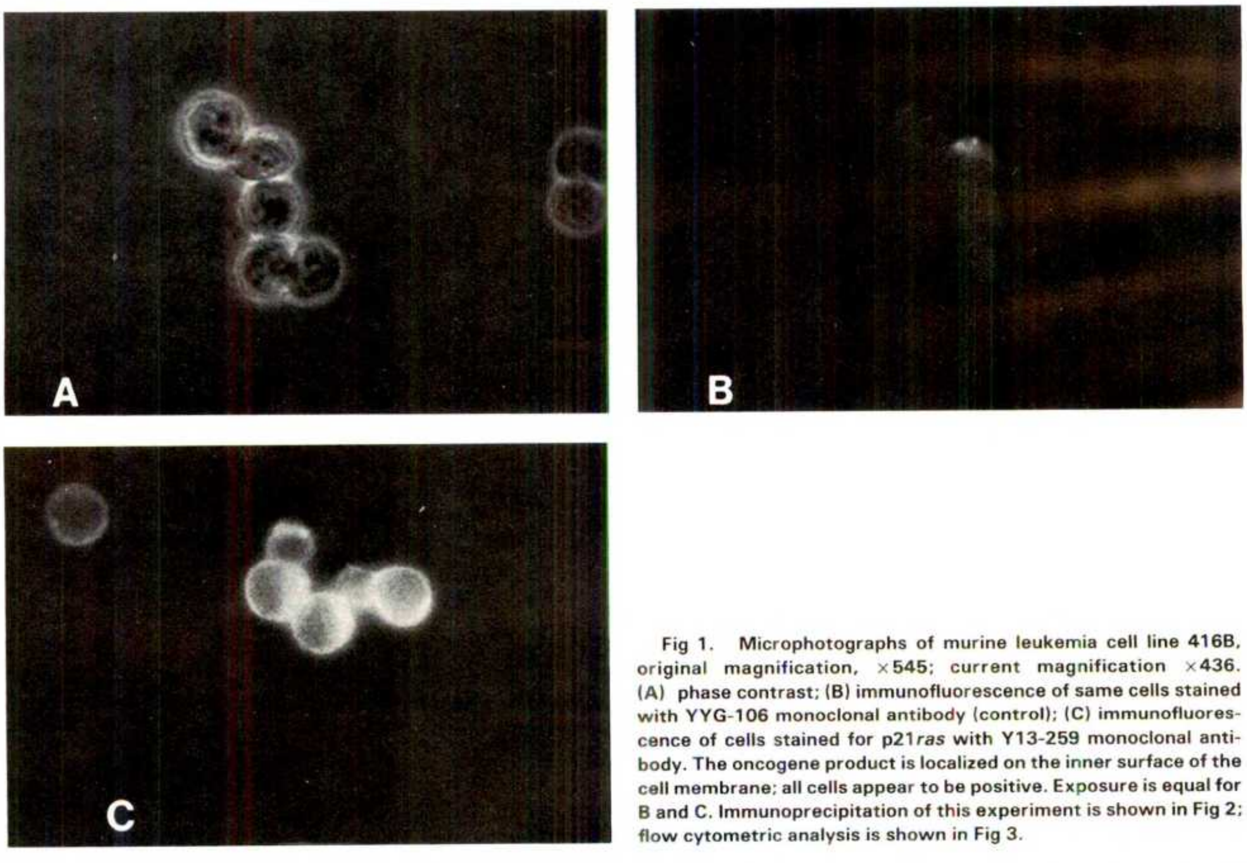

Fig 1. Microphotographs of murine leukemia cell line 416B, original magnification, ×545; current magnification ×436. (A) phase contrast; (B) immunofluorescence of same cells stained with YYG-106 monoclonal antibody (control); (C) immunofluorescence of cells stained for p21*ras* with Y13-259 monoclonal antibody. The oncogene product is localized on the inner surface of the cell membrane; all cells appear to be positive. Exposure is equal for B and C. Immunoprecipitation of this experiment is shown in Fig 2; flow cytometric analysis is shown in Fig 3.

elevated gene expression, as in the Y1 adrenal carcinoma cell line[22] or in 416B murine hematopoietic precursor cells[23-24] in which p21 Ki-*ras* is overproduced. Similarly, the normal Ha-*ras* gene can transform NIH 3T3 cells if it is ligated to a retroviral strong transcriptional promoter.[25,26]

A flow cytometric assay of immunofluorescence in which DNA content can be measured simultaneously would be useful to determine the range of p21*ras* levels in human leukemia and lymphoma, to detect subpopulations of tumor cells with markedly high levels of p21*ras*, and to correlate *ras* gene expression with cell cycle phases. Hematopoietic malignancies provide an excellent model for the study of the activity of cellular oncogenes in a context of known defects in cell proliferation and differentiation.

MATERIALS AND METHODS

Monoclonal antibodies. A panel of rat monoclonal antibodies that precipitate p21*ras* was developed by Furth et al.[27] Y13-259 is a broad spectrum monoclonal antibody that binds p21 encoded by the Ha-*ras*, Ki-*ras*, and N-*ras* genes. YYG-106, used as a control antibody in these experiments, is a rat monoclonal antibody directed against murine hematopoietic colony-stimulating factor.

Leukemic cell lines. Cells (416B) were grown in a 1:1 mixture of Dulbecco's modified Eagle's medium (DMEM) and Ham F12 medium supplemented with antibiotics and 20% horse serum (Flow Laboratories, Rockville, Md). P-12 and KG-1 were grown in RPMI 1640 medium supplemented with 2 mmol/L of glutamine, 1% antibiotics and 10% heated fetal calf serum (FCS). All cells were maintained at 37 °C in a 5% CO_2 humidified atmosphere.

Simultaneous staining of DNA and intracytoplasmic antigens. Leukemic cell suspensions were fixed in 100% methanol for ten minutes at −20 °C and were stained by a three-step indirect method. Fifty microliters of Y13-259 at a concentration of 50 μg/mL were incubated with 1 to 2 × 10^6 cells (minimum cell number was 0.5 × 10^6). This was followed by rabbit anti-rat IgG (Cappel, Cochranville, Pa) at a dilution of 1:200, and fluorescein isothiocyanate (FITC)-goat anti-rabbit IgG (B&M, Indianapolis) at 1:40. All of the reagents were added for 30 minutes at 4 °C. The cells were then stained with propidium iodide after treatment with RNase as previously described.[28] The fixation and staining conditions were developed after extensive experiments (data not shown) conducted to enhance the sensitivity of the assay for the detection of low levels of p21*ras*.

A computer-interfaced research cytofluorograph (model FC201, Ortho Instruments, Westwood, Mass) with an argon-ion laser (model 75, Lexel, Palo Alto, Calif) tuned to 488 nm and operated at 30 mW was used. The signals were amplified on a linear scale. FITC green fluorescence (tertiary antibody-anti-p21*ras*), propidium iodide red fluorescence (DNA) and red pulse width (nuclear diame-

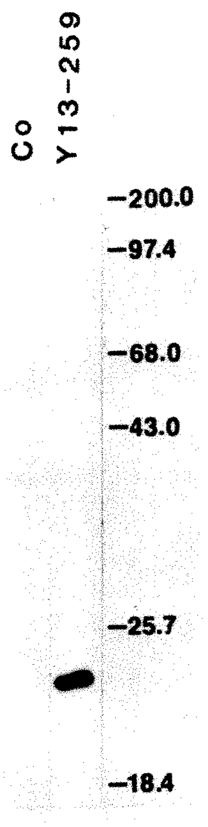

Fig 2. Radioimmunoprecipitation of murine leukemia cell line 416B with rat monoclonal antibody Y13-259 and normal rat IgG (control). The antibody precipitates p21*ras*. The same experiment is evaluated by immunofluorescence in Fig 1 and by flow cytometry in Fig 3.

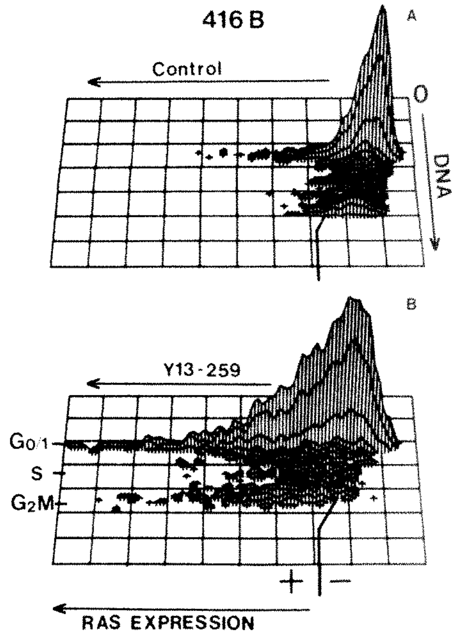

Fig 3. Computer-drawn histograms of correlated measurements of cellular DNA content and p21*ras* immunofluorescence of murine leukemia cell line 416B: *y*-axis, DNA content (cell cycle stages $G_{0/1}$-S-G_2M); *x*-axis, indirect immunofluorescence of control antibody YYG-106 (A) and Y13-259 directed against p21*ras* (B); *z*-axis, cell number. Red fluorescence (propidium iodide) pulse width was also measured simultaneously to distinguish single cells from cell aggregates (not shown). Data shown here are gated for single cells only; (−) designates negative and (+) designates positive immunofluorescence. Microphotographs of this experiment are shown in Fig 1B and C and immunoprecipitation is shown in Fig 2. DNA measurements show progression of cells from $G_{0/1}$ to S and G_2M. Almost all cells are positive for p21*ras*, with no cell cycle-related increase of *ras* expression in these exponentially growing cells. Considerable heterogeneity is apparent in all cell cycle phases, particularly in G_1.

ter) were measured in 5,000 cells per sample and stored as correlated measurements in a Nova 1220 minicomputer (Data General, Southwood, Mass). Red pulse width was used to distinguish single cells from cell aggregates. Data analysis was performed with a Tektronix 4010-1 graphic terminal (Tektronix, Beaverton, Ore) using computer programs developed by Sharpless.[29]

Immunofluorescence. Leukemic cells were stained by the three-step indirect method described above without counterstaining for DNA. Cell suspensions were mounted under coverslips with Hydromount (National Diagnostics, Somerville, NJ) and examined with appropriate filter combinations for fluorescein.

Immunoprecipitation of p21ras proteins. Cells were labeled by metabolic incorporation of ^{35}S-methionine (0.1 mCi/mL in methionine-free medium supplemented with 5% dialyzed fetal bovine serum) for five hours at 37 °C. The cells were washed and then incubated for a further period of one hour in complete medium containing unlabeled methionine and 10% fetal bovine serum. Cell lysates were prepared in a buffer containing 1% Triton X-100 (Sigma Chemical, St Louis) and 0.5% Na deoxycholate. Portions containing 10^7 cpm of incorporated ^{35}S-methionine (assessed by precipitation with trichloroacetic acid) were diluted to 0.3 mL with lysis buffer, and Na dodecyl sulfate (SDS) was added to a final concentration of 0.25% (wt/vol). One microgram of monoclonal anti-*ras* rat IgG or purified normal rat immunoglobulin was added to each tube, and reactions were incubated at 4 °C for 18 hours. Immune complexes were collected by addition of formalin-fixed *S aureus* precoated with rabbit antibodies against rat IgG, for one hour at 4 °C. The bacteria were washed extensively, and labeled proteins were eluted by boiling in sample buffer containing SDS and 2-mercaptoethanol. The samples were analyzed by electrophoresis on 15% polyacrylamide gels containing 0.1% SDS, and labeled proteins were detected by fluorography.

RESULTS

Three different cell lines were used to develop the quantitative flow cytometric assay of intracytoplasmic immunofluorescence: the murine hematopoietic precursor cell line 416B, the human myeloblastic leukemia line KG-1, and the human T cell lymphoblastic leukemia line P-12. Fig 1 shows phase contrast, control antibody YYG-106, and specific staining with anti-p21*ras* antibody Y13-259 in 416B cells. The photomicrographs were matched for magnification and for times of exposure and development. Immunoprecipitation of ^{35}S-methionine–labeled 416B cells is shown in Fig 2: Y13-259 precipitates a single band in the 21-kd region. The corresponding flow cytometric histograms are shown in Fig 3: the upper histogram shows proliferating cells in the G_1-S-G_2M phases of the cell cycle (y-axis = DNA), and defines the background fluorescence (x-axis = immunofluorescence of YYG-106). The lower histogram shows positive p21*ras* immunofluorescence in >90% of the cells. G_1 cells exhibit considerable heterogeneity, with cells expressing

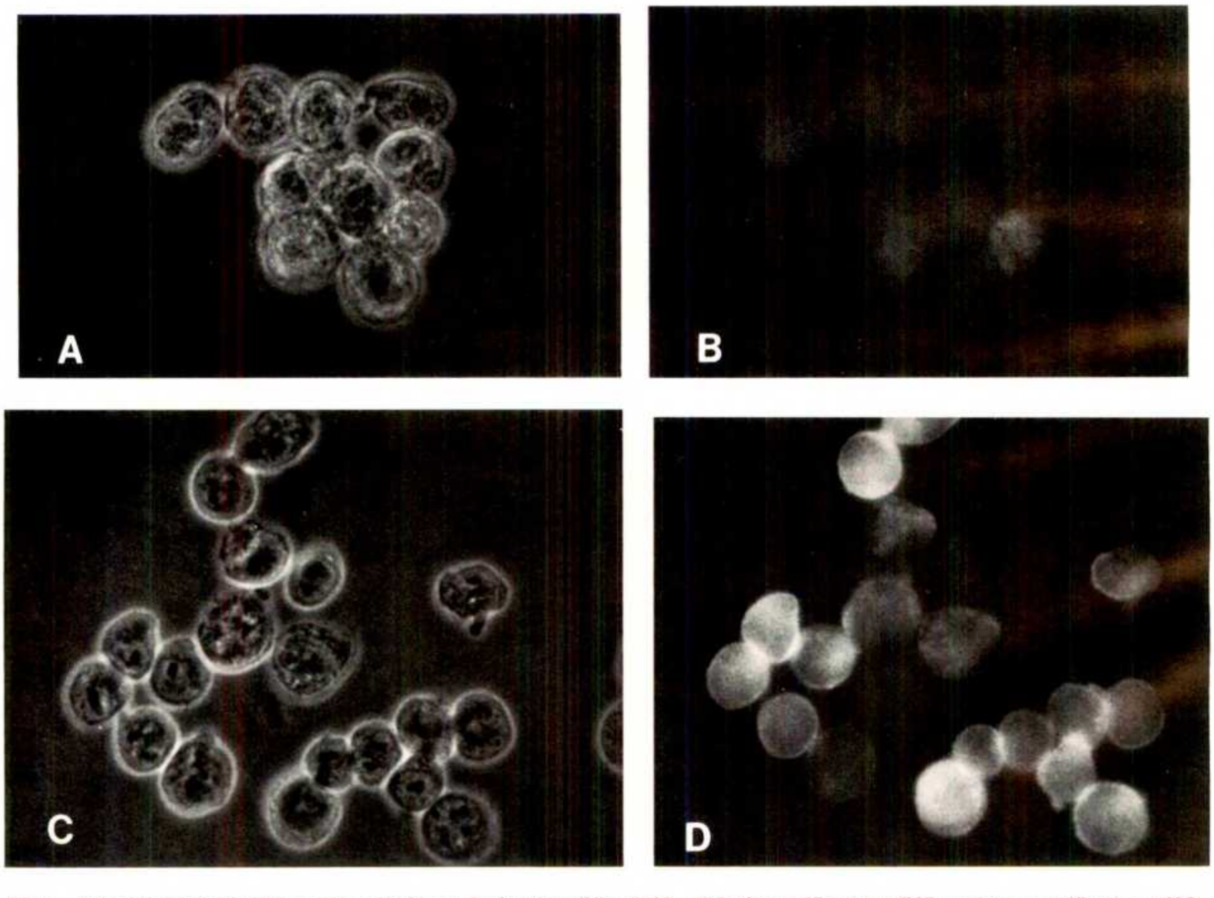

Fig 4. Microphotographs of human lymphoblastic leukemia cell line P-12, original magnification ×545; current magnification ×420. (A and C) Phase contrast of cells stained with control antibody YYG-106 (B), and anti-p21*ras* antibody Y13-259 (D), respectively. Exposure is equal for B and D. Immunoprecipitation of this experiment is shown in Fig 5, lane 1; flow cytometric analysis is shown in Fig 6.

low, intermediate, and high amounts of the cellular *ras* gene protein. There is no apparent increase in p21*ras* when the cells progress to S and G_2M if the increase in unspecific background fluorescence due to increased cell size is taken into consideration.

The human myeloid leukemic cell line KG-1 was also stained with Y13-259 and YYG-106. Approximately 60% of the cells in all cell cycle phases had fluorescence that was indistinguishable from background level. Forty percent of the cells were positive, but there was much less heterogeneity in G_1 than was found in 416B cells. Again, no increase in p21*ras* was seen during cell cycle progression (data not shown).

N-*ras*–transforming gene sequences were identified in P-12 human lymphoblastic leukemic cells in a transfection assay.[3] Fig 4 shows the typical ring pattern of p21*ras* immunofluorescence. Fig 5 depicts a one-dimensional gel in which P-12 cells were immunoprecipitated using two different monoclonal antibodies directed against p21*ras*. Y13-238 immunoprecipitates human p21 Ha-*ras* and p21 Ki-*ras* but does not immunoprecipitate p21 N-*ras* (Furth et al, unpublished observations). The band precipitated by Y13-238, corresponding primarily to p21 Ki-*ras*, was weak, but the flow cytometric assay using this antibody was positive (data not shown). A double band of p21*ras* appeared when P-12 cells were immunoprecipitated with Y13-259, since P-12 cells produce both a normal and an altered form of p21 N-*ras* with slightly different electrophoretic mobilities.[3,4] Fig 6 shows the corresponding DNA/p21*ras* histograms: ~25% of the cells in all cell cycle phases were negative, whereas the remaining cells were positive in the flow cytometric immunofluorescence assay.

The staining procedure used in these experiments yielded minimal background fluorescence, and permitted the low levels of p21*ras* found in the human leukemic cells to be detected. The assay has a greater sensitivity than the method previously described by Andreeff et al for the measurement of p21*ras* in leukemic cells.[30]

DISCUSSION

Specific binding of a monoclonal antibody directed against the protein product of the three cellular *ras* oncogenes (p21*ras*) can be measured in a quantitative flow cytometric assay of immunofluorescence. The presence of p21*ras* was confirmed by direct microscopy in three hematopoietic cell lines and by immunoprecipitation experiments using the same antibody. Oncogene expression can be directly correlated to the cell cycle since total DNA content can be determined simultaneously.

The role of p21*ras* in cell transformation and its possible relationship to the cell cycle are not completely understood.

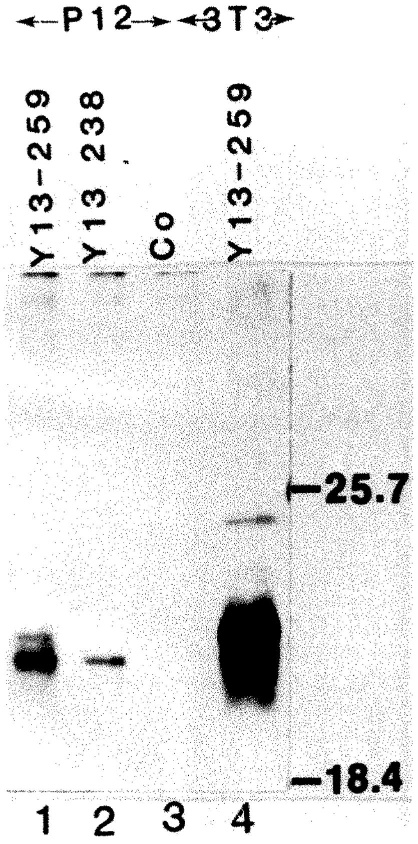

Fig 5. Radioimmunoprecipitation of human lymphoblastic leukemia cell line P-12 with antibodies against p21*ras* and control rat IgG (lanes 1 through 3). Lane 4 shows results of anti-p21*ras* antibody Y13-259 with *ras*-transfected NIH 3T3 cells.

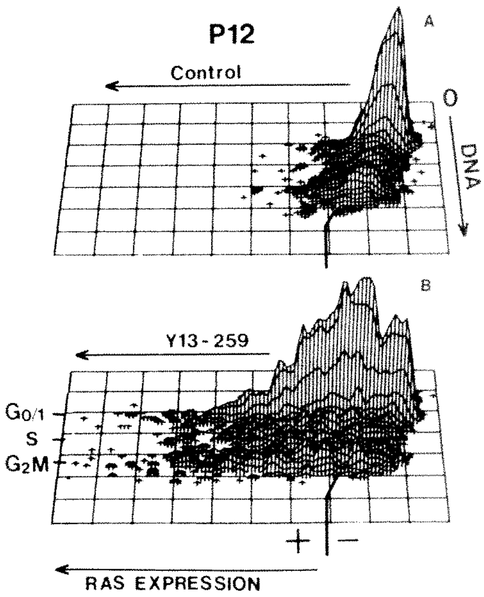

Fig 6. Computer-drawn histograms of correlated measurements of cellular DNA content and p21*ras* immunofluorescence of human lymphoblastic leukemia cell line P-12: *y*-axis, DNA content (cell cycle stages $G_{0/1}$-S-G_2M); *x*-axis, indirect immunofluorescence of control antibody YYG-106 (A) and Y13-259 directed against p21*ras* (B); *z*-axis, cell number; (–) negative and (+) positive immunofluorescence. Microphotographs of the immunofluorescence of this experiment are shown in Fig 4(B) and (D), respectively. DNA distribution shows high proliferation. Approximately 75% of cells are positive for p21*ras*, with no cell cycle related increase of *ras* expression. Heterogeneity of *ras* expression with non-Gaussian distribution is apparent in all cell cycle phases.

The ability of p21*ras* to bind guanine nucleotides[10] is probably associated with effective cell transformation. Early work by Scolnick et al showed that a temperature-sensitive mutant of the Kirsten murine sarcoma virus was temperature sensitive for transformation and that the v-Ki-*ras* protein was also temperature sensitive for guanine nucleotide binding.[31] More recently, several groups have reported that the T24 transforming *ras* protein, which has an amino acid substitution at position 12, had significantly reduced GTPase activity when compared with its normal counterpart.[11-14] Sweet et al suggested that the transforming capability of the altered protein might directly reflect prolonged stimulation of a normal cellular function whose termination signal would be the presence of GDP subsequent to GTP binding.[12] Induction of a transformed phenotype has also been associated with elevated levels of the normal *ras* protein.[22-26]

P21*ras* was found in all cell cycle phases in three hematopoietic cell lines by the flow cytometric assay. There was considerable heterogeneity in the G_1 compartment, in which some cells had a larger amount of p21*ras* than was found in any S phase cell whereas other cells were in a lower range of positivity. Cells in early and late G_1 may have different amounts of p21*ras*. It is also possible that a subpopulation requires an overproduction of p21*ras* during G_1 in order to maintain a constant level of cell proliferation. Recent studies by several investigators indicate that p21*ras* may be involved in the regulation of DNA synthesis. Campisi et al have reported that the level of c-*ras* transcripts rises in the later part of G_1 in mouse fibroblasts stimulated by the sequential action of platelet-derived growth factor, epidermal growth factor, and somatomedin C, and continues to increase as the cells enter S phase.[32] Quiescent NIH 3T3 cells growing in serum-depleted medium were transformed directly following microinjection of purified p21 Ha-*ras* and entered S phase as measured by the incorporation of ^{3}H-thymidine.[33] NIH 3T3 cells induced to divide by the addition of serum were unable to enter S if p21*ras* was neutralized by an anti-p21*ras* monoclonal antibody.[34]

The simultaneous flow cytometric assay of immunofluorescence and total DNA content described here is a powerful tool for the elucidation of the relationship between oncogene expression and the cell cycle. The assay allows oncogene expression to be measured in populations of single intact cells where cell heterogeneity is maintained, requires very few cells per sample, and directly correlates oncogene expression with cell kinetic data.

CFU-M–Derived Human Megakaryocytes Synthesize Glycoproteins IIb and IIIa

By Robert B. Jenkins, William L. Nichols, Kenneth G. Mann, and Lawrence A. Solberg, Jr

Human megakaryocytes have been shown by immunofluorescent techniques to express platelet glycoprotein IIb/IIIa antigen. We report evidence that megakaryocytes derived from human committed megakaryocytic progenitor cells in vitro (CFU-M) synthesize glycoproteins IIb and IIIa. Nonadherent light-density human bone marrow cells were cultured in human plasma and methylcellulose using conditions that promote large megakaryocytic colonies. On day 13 the megakaryocytic colonies were picked, pooled, and pulsed with ^{35}S-methionine in methionine-free media. Populations of approximately 100,000 cells with ≥95% viability and containing 70% to 90% megakaryocytes were obtained reliably for study. After the radioactive pulse, the cell suspension was solubilized with nonionic detergent. To reduce nonspecific binding of ^{35}S-labeled proteins to agarose, the lysate was chromatographed sequentially on glycine-quenched Affi-gel and antihuman factor X–Sepharose. The unbound material from these resins was then chromatographed on an antiglycoprotein IIb/IIIa monoclonal antibody resin (HP1-1D–Sepharose) or on a control monoclonal antibody resin. Bound fractions were eluted and analyzed by polyacrylamide gel electrophoresis and autoradiography. Autoradiograms of diethylamine eluates from HP1-1D–Sepharose revealed two labeled proteins with electrophoretic mobilities identical with those of human platelet membrane glycoproteins IIb and IIIa, isolated using similar conditions. Autoradiograms of material synthesized by control macrophages from the same donors revealed no significant labeling of proteins in the glycoprotein IIb/IIIa molecular weight range, nor were such proteins bound by HP1-1D–Sepharose. Our observations show that protein synthesis by CFU-M–derived human megakaryocytes can be readily studied using a small amount of bone marrow aspirate as starting material. This approach will allow the study of protein synthesis by megakaryocytes from normal subjects or from subjects with clinical disorders, and it will circumvent the need to obtain large amounts of bone marrow to prepare enriched populations of megakaryocytes.

© 1986 Grune & Stratton, Inc.

THE STUDY of protein synthesis by normal human megakaryocytes has been hampered by the difficulty in obtaining sufficiently large populations of cells markedly enriched for megakaryocytes. Other investigators have reported that von Willebrand factor, actin, coagulation factor V, and fibrinogen are synthesized by megakaryocytes enriched from guinea pig bone marrow[1-4] and that platelet factor 4 is synthesized by megakaryocytes enriched from rabbit bone marrow.[5] These studies have depended on physical separation techniques for enriching megakaryocytes directly from bone marrow such as density gradient centrifugation, sedimentation velocity, and centrifugal elutriation. Recently, the synthesis of platelet glycoproteins IIb and IIIa by human neoplastic cell lines has been reported.[6,7] Also, Rabellino et al[8] have reported preliminary evidence that megakaryocytes enriched from human marrow and placed in short-term liquid suspension culture synthesize platelet glycoproteins IIb and IIIa.

The aims of this study are to show that (1) large numbers of enriched human megakaryocytes can be obtained from colonies formed in vitro by committed megakaryocytic progenitors (CFU-M) proliferating under conditions that promote large megakaryocytic colonies and (2) these populations of megakaryocytes can be used for the study of protein synthesis. We report here the first evidence that normal human CFU-M–derived megakaryocytes can synthesize platelet glycoproteins IIb and IIIa. We believe that the linkage of in vitro culture studies of human megakaryocytopoiesis and the study of protein synthesis will help set the stage for an increased understanding of normal and disturbed megakaryocytopoiesis in vivo.

MATERIALS AND METHODS

Bone marrow culture. Bone marrow aspirates from consenting normal donors were collected into sterile glass tubes containing preservative-free sodium heparin (O'Neal, Jones and Feldman, St Louis). A mononuclear marrow cell suspension of density less than 1.077 g/mL was isolated, diluted, and plated into a plasma/methylcellulose cell culture system as previously described.[9,10]

Cells were cultured in 30% plasma from a patient with aplastic anemia and 10% conditioned medium from peripheral blood leukocytes stimulated by phytohemagglutinin (PHA-LCM). Megakaryocytic colonies were identified by inverted microscopy according to previously published criteria.[9-11] Moreover, in analyzing the cellular content of 500 picked colonies derived under these culture conditions, approximately 90% of the pooled cells were megakaryocytic as defined by Wright-Giemsa staining and by immunofluorescent staining for human coagulation factor V, platelet factor 4, von Willebrand factor, β-thromboglobulin, and platelet glycoprotein IIb/IIIa.[12,13] Cells were also cultured in 30% fetal calf serum (Hyclone, Logan, Utah) and 10% PHA-CLM to stimulate macrophage colony growth. Plating densities of 100,000 cells/mL were used to reduce contamination of colonies by surrounding cells.

On day 13 of culture, the megakaryocytic (Fig 1) or macrophage colonies were picked with a finely drawn, sterile Pasteur pipette and pooled into 200 μL of filter-sterilized methionine-free RPMI 1640 (KC-Biological, Lenexa, Kan) containing 1% bovine serum albumin and buffered with 25 mol/L HEPES at pH 7.25 (medium A). Aliquots of the pooled cells were used for cell counts, differentials after Wright-Giemsa staining, and viability determinations by trypan blue exclusion. The remainder of the pooled cells (50,000 to 150,000 cells) were diluted with 800 μL medium A and incubated for 2½ to three days at 37 °C in 5% CO_2 with 0.5 mCi ^{35}S-methionine

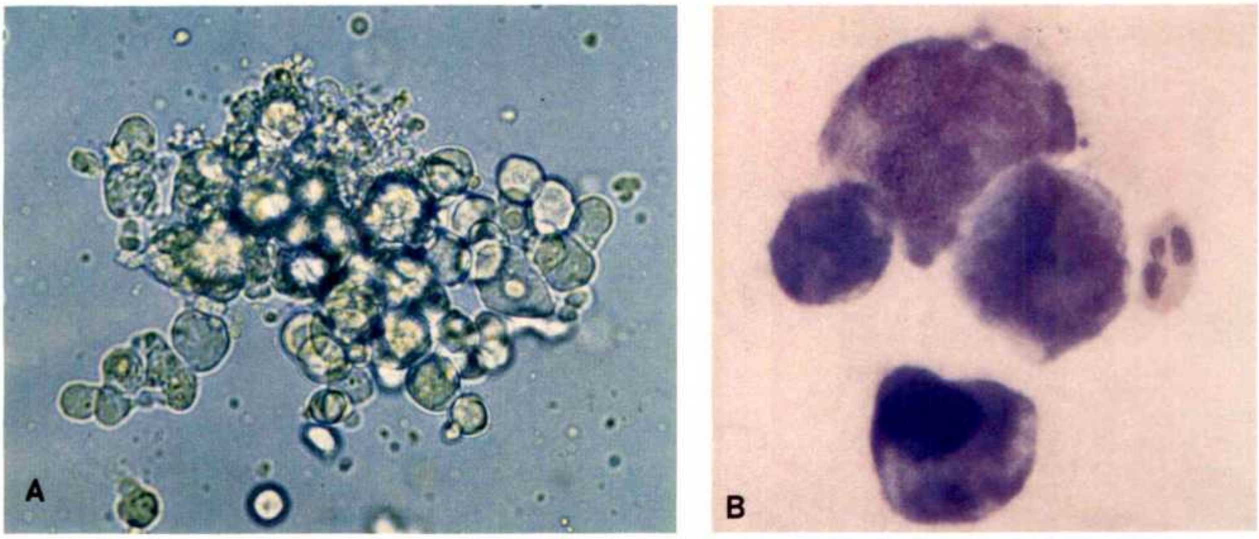

Fig 1. Typical human megakaryocytic colonies from a normal bone marrow cultured as described in Materials and Methods. (A) An in situ megakaryocytic colony visualized by inverted microscopy (original magnification ×325; current magnification ×211). (B) A picked megakaryocytic colony smeared onto a glass slide and stained by the Wright-Giemsa method (original magnification ×800; current magnification ×520). Four megakaryocytes and one neutrophil are present in the field.

(Amersham Corp, Arlington Heights, Ill; 1500 Ci/mmol). After the incubation period, the cells and medium were transferred to a glass tube coated with medium A, and Triton X-100 (J.T. Baker, Phillipsburg, NJ) was added to a final concentration of 1%. The resultant lysates were frozen at −70 °C until immunoisolation was performed.

Preparation of HP1-1D–Sepharose immunoaffinity resin. HP1-1D murine monoclonal antibody has been previously described.[13-15] The antibody is an IgG and has specificity for an epitope expressed by the human platelet membrane glycoprotein IIb/IIIa complex. HP1-1D IgG was isolated from pooled mouse ascites fluid by gel filtration chromatography[16] and was concentrated by ultrafiltration in coupling buffer (0.2 mol/L NaCl, 0.1 mol/L $NaHCO_3$, pH 8.5). CH-Sepharose 4B, activated with *N*-hydroxysuccinimide, was obtained from Pharmacia Fine Chemicals (Uppsala, Sweden). Three grams of the resin were washed sequentially with 300 mL 0.001 N HCl, 300 mL water, and 30 mL coupling buffer. The washed resin was stirred for one hour at 22 °C with 13.2 mg HP1-1D IgG in coupling buffer (total volume approximately 30 mL), then 0.1 vol 1 mol/L Tris-Cl (pH 8) was added and the slurry was stirred for an additional hour before washing with approximately 5 volumes of 0.15 *M* NaCl, 0.02 mol/L Tris-Cl, pH 7.4. The resin was finally washed with approximately 5 vol of 50% glycerol, 0.01 mol/L Tris-borate, and 0.001 mol/L $CaCl_2$, pH 8.4, and was stored at −20 °C in this buffer. The efficiency of IgG coupling to activated CH-Sepharose 4B was 88% as determined spectrophotometrically (A_{280} applied − A_{280} eluted).

Immunoaffinity isolation of human platelet glycoproteins IIb and IIIa. Platelet membrane vesicles were prepared from fresh platelet-rich plasma obtained from the Mayo Clinic Blood Bank, using a modified glycerol-hypotonic lysis technique.[17] Pelleted platelet membrane vesicles (4.7 mg protein) were suspended at 22 °C in 2 mL 0.15 mol/L NaCl and 0.01 mol/L Tris-Cl, pH 7.4 (Tris-saline), which contained 1% CHAPS detergent (3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate; Calbiochem-Behring Corp, La Jolla, Calif). Aliquots were removed from the solubilized membrane preparation before and after centrifugation (20,000 g, 15 minutes, 22 °C) for protein quantitation as described.[17] The remainder of the solubilized, centrifuged supernatant (extracted membranes that contained 72% of the membrane protein originally present) was diluted with 1 vol of Tris-saline buffer, then applied at 22 °C to a column of HP1-1D–Sepharose (plastic disposable 12-mL syringe with a porous polyethylene frit, containing 5 mL resin washed with Tris-saline and 0.1% CHAPS, pH 7.4). Following incubation (60 minutes, 22 °C), elution fractions of 2 mL were collected, using a flow rate of 1 mL/min, as the column was washed sequentially at 22 °C with approximately 20-mL vol of the following buffers: (1) Tris-saline and 0.1% CHAPS, pH 7.4; (2) Tris-saline, 0.1% CHAPS, and 5 mmol/L sodium EDTA, pH 7.4; (3) 1.5 mol/L NaCl, 0.01 mol/L Tris-Cl, and 0.1% CHAPS, pH 7.4; (4) 1.5 mol/L NaCl, 0.1 mol/L glycine-Cl, and 0.1% CHAPS, pH 3.0 (each fraction collected in 1-mL of 1 mol/L Tris-Cl, pH 8.0); (5) 3.0 mol/L NaSCN, Tris-saline, and 0.1% CHAPS, pH 7.2; (6) Tris-saline and 0.1% CHAPS, pH 7.4; and (7) 0.05 mol/L diethylamine and 0.1% CHAPS, pH 11.5 (each fraction collected in 2-mL fractions of 1 mol/L Tris-Cl, pH 8.0). Fractions were monitored spectrophotometrically (A_{280}) and by polyacrylamide gradient gel electrophoretic analysis in the presence of sodium dodecyl sulfate (SDS).[17]

For the latter analysis, pooled elution fractions were dialyzed into Tris-saline and 0.01% CHAPS and, if necessary, concentrated by ultrafiltration. Nonreduced protein samples were prepared by incubation (30 minutes, 37 °C) following the addition of *N*-ethylmaleimide to a concentration of 5 mmol/L. Prior to electrophoresis, sample preparation buffer was added to yield final concentrations of 2.5% dodecyl sulfate, 10% glycerol, 0.01% bromphenol blue, and twofold-diluted stacking gel buffer with or without 5% β-mercaptoethanol. After additional incubation (60 minutes, 37 °C), samples were electrophoresed in polyacrylamide linear gradient slab gels, and proteins were detected with Coomassie brilliant blue R-250 staining as described[17] except that (1) 1.5-mm thick slabs were used, (2) the acrylamide gradient was 4% to 12%, and (3) the lower electrode buffer consisted of 0.04 mol/L Tris-borate, pH 8.6. Gels were calibrated with reduced protein molecular weight standards obtained from Bio-Rad Laboratories (Richmond, Calif): myosin heavy chain (210,000), β-galactosidase (116,000), phosphorylase b (92,500), bovine serum albumin (66,000), ovalbumin (43,000), carbonic anhydrase (30,000), and cytochrome c (12,500). An additional standard consisted of platelet membrane vesicle proteins treated at pH 7.4 with 5 mmol/L *N*-ethylmaleimide (30 minutes, 37 °C) prior to sedimentation in Tris-saline and solubilization (60 minutes, 37 °C) in electrophoresis sample preparation buffer (±5% β-mercaptoethanol).

Immunoaffinity isolation of megakaryocytic glycoproteins IIb and IIIa. The strategy used for the immunoisolation of megakaryocytic glycoproteins IIb and IIIa is outlined. The ^{35}S-lysates were sequentially prechromatographed on 0.5 mL of glycine-quenched Affigel-10 resin (Bio-Rad) and on 0.5 mL of mouse monoclonal antihuman factor X (HFX)-Sepharose (kindly supplied by Dr W.R. Church, Mayo Clinic) to reduce nonspecific binding of ^{35}S-labeled proteins. The resultant anti–HFX-Sepharose flow-through was divided equally into two aliquots for further immunoisolation chromatography using either HP1-1D–Sepharose (antihuman platelet glycoprotein IIb/IIIa) or control mouse monoclonal antihuman antithrombin III (HAT III) IgG coupled to Sepharose (kindly supplied by Dr M.E. Nesheim, Mayo Clinic). One-half milliliter aliquots of each resin were equilibrated with 0.02 mol/L imidazole, (J.T. Baker, Phillipsburg, NJ) 5 m*M* $CaCl_2$, pH 6.5 (Imid-$CaCl_2$). The equilibrated resins were then placed into medium A–coated glass tubes, and half of the ^{35}S-labeled flow-through from the anti–HFX-Sepharose was added to each. The tubes were sealed and placed at 22 °C on a rocking platform for 60 minutes. The mixtures were then poured into disposable minicolumns (Bio-Rad) and the flow-through material was eluted with approximately 30 mL Imid-$CaCl_2$ until the counts per minute per milliliter was less than 200. Bound materials were released stepwise using 10 mL 1.5 mol/L NaCl in Imid-$CaCl_2$, 10 mL 3.0 mol/L NaSCN in Imid-$CaCl_2$, and finally, 10 mL 0.05 mol/L diethylamine, 0.1% TritonX-100. One-milliliter fractions were collected and monitored by scintillation counting with a Beckman LS-7500 liquid scintillation counter (Beckman Instruments, Inc, Fullerton, Calif) using Beckman Redi-Solv HP as the scintillant. The diethylamine-containing fractions were immediately neutralized by the addition of 300 μL 1.0 mol/L Tris-HCl, pH 7.4. The peak fractions from each eluate were pooled, and, in experiment 1, aliquots were incubated with 5 mmol/L *N*-ethylmaleimide for 30 minutes at 37 °C. To all samples a final concentration of 0.1% SDS was added, and then the samples were dialyzed overnight *v* 0.1% SDS with one change of dialysate. All samples were then lyophilized in preparation for electrophoretic analysis.

Electrophoresis/autoradiography. Lyophilized ^{35}S-samples were dissolved in 150 μL sample preparation buffer (2% SDS; 10% glycerol; 0.06 mol/L Tris-HCl, pH 6.8; and 0.01% bromphenol blue). Reduced samples were prepared by the addition of a final concentration of 5% β-mercaptoethanol, then both reduced and unreduced samples were heated at 90 °C for ten minutes. Electrophoresis was carried out in 5% to 15% linear gradient polyacrylamide slab gels (4% acrylamide stacking gel) with the buffers described by Laemmli.[18] Approximately equivalent counts were added to each well on the slab gel. ^{125}I-protein molecular weight standards were kindly supplied by Mr G.J. Knutson (Mayo Clinic) and were used to calibrate the gels. Following electrophoresis, the gels were fixed in glacial acetic acid-ethanol-water (3:8:9, vol:vol) for 30 minutes, then placed in En^{3}Hance (New England Nuclear, Boston) for 30 minutes, followed by water rehydration for at least 45 minutes. The treated gels were mounted on chromatography paper (Bio-Rad) and dried on a slab gel drier. Each dried gel was placed inside a wafer rigid-form x-ray cassette lined with Dupont Lightning Plus intensifying screens with Kodak XAR-5 x-ray film for exposure at −70 °C. The time of exposure was adjusted according to the radioactivity of the samples applied to the gel.

RESULTS

Characterization of pooled colonies. To obtain large numbers of human megakaryocytes for the biosynthetic experiments described in the next section, CFU-M–derived megakaryocytic colonies were sterilely picked and pooled into a methionine-free serum-free medium. Table 1 summarizes the differential cell counts of pooled colonies picked from culture of marrow cells obtained from three separate normal donors. The megakaryocytic colonies were picked from 30 to 38 tissue culture plates from each donor. The average colony formation from the three donors ranged from 31 to 163 CFU-M–derived colonies per tissue culture plate (100,000 plated cells). Individual megakaryocytic colonies contained from five to 250 cells. The average number of cells per megakaryocytic colony was 105 for experiment 1, 25 for experiment 2, and 92 for experiment 3. One hundred thousand cells with 95% viability by trypan blue exclusion and consisting of 70% to 90% megakaryocytes were typically obtained. Between 5% and 16% of the cells were macrophages. Macrophages are present in the megakaryocyte population because the conditions used to support megakaryocytic colony formation also support some macrophage colony growth and some macrophages are picked accidentally. The variability in differentials between donors also reflects the donor-to-donor variation in the number, type, and density of colony growth in the cultures.

Table 1 also illustrates that macrophage colonies from the same donors can be picked and pooled with minimal megakaryocytic contamination. For control purposes in the biosynthetic experiments, the number of macrophages picked and pooled into methionine-free, serum-free medium was approximately equal to the number of contaminating macro-

Table 1. Results of Picking and Radiolabeling Megakaryocytic or Macrophage Colonies

Experiment	Suspension	Cells Picked	Mega	Macro	NRBC	PMN/Other	TCA-Precipitable cpm
1	Mega	130,000	72.3%	16.6%	5.5%	5.6%	2.70×10^7
	Macro*	30,000	0.9%	60.7%	26.6%	11.6%	1.43×10^7
2	Mega	150,000	89.1%	7.7%	3.2%	—	1.76×10^7
	Macro	15,000	1.6%	96.0%	2.4%	—	3.82×10^6
3	Mega	86,000	88.4%	5.3%	3.4%	2.8%	ND
	Macro	44,000	0.4%	95.0%	1.8%	2.8%	ND

Abbreviations: Mega, megakarocyte; Macro, macrophage; NRBC, Nucleated erythroid cell; PMN, polymorphonuclear leukocyte; ND, not determined.

*Erythropoietin (2 U/mL) was present in the medium from which the macrophage colonies were picked.

phages present in the picked and pooled megakaryocytic populations.

The picked and pooled cells from experiments 1 and 2 (Table 1) were incubated with 0.5 mCi ^{35}S-methionine for 2½ days, then the cells and medium were lysed together, and aliquots of the lysates were treated with 10% trichloroacetic acid (TCA) to determine the amount of incorporated radioactivity (Table 1). The remaining portions of the cell lysates were stored at −70 °C until used for immunoaffinity isolation of ^{35}S-labeled proteins.

Immunoaffinity isolation of platelet membrane glycoproteins IIb and IIIa. Before performing biosynthetic experiments with megakaryocytes, we characterized the conditions required for the immunofractionation of platelet glycoproteins IIb and IIIa on HP1-1D–Sepharose immunoaffinity resin. For this characterization, we used human platelet membrane preparations extracted with CHAPS detergent. Figure 2 shows the results of polyacrylamide gel electrophoresis of detergent-extracted platelet membrane vesicles immunofractionated on HP1-1D–Sepharose. As compared with the protein composition of the material applied to the HP1-1D–Sepharose column (electrophoresis lane 2), the column flow-through material (lane 3) appeared depleted of two proteins with apparent reduced molecular weights of 120,000 and 100,000. This observation suggested that HP1-1D–Sepharose bound most of the glycoprotein IIb/IIIa antigen contained in the material that was applied to the column. Subsequent washing of the column (buffers 2 through 6, Materials and Methods) did not result in the elution of significant protein (A_{280}) nor in detectable protein bands upon polyacrylamide gel electrophoresis (data not shown). The platelet membrane proteins specifically bound to HP1-1D–Sepharose were eluted with diethylamine (buffer 7, Materials and Methods). The diethylamine eluate represented approximately 12% of the protein material applied (A_{280}). Since one of the unique properties of glycoproteins IIb and IIIa is their characteristic change in electrophoretic migration after reduction of disulfide bonds,[19] we analyzed the eluted proteins before and after disulfide bond reduction. Electrophoresis of the nonreduced diethylamine eluate (lane 5) revealed two major proteins with apparent molecular weights of 135,000 and 80,000, whereas with reduction of disulfide bonds, the two proteins migrated electrophoretically with apparent molecular weights of 120,000 and 100,000, respectively (lane 4). Based upon these observations, similar immunofractionation conditions were used to study ^{35}S-labeled megakaryocytic proteins that specifically bound to HP1-1D–Sepharose.

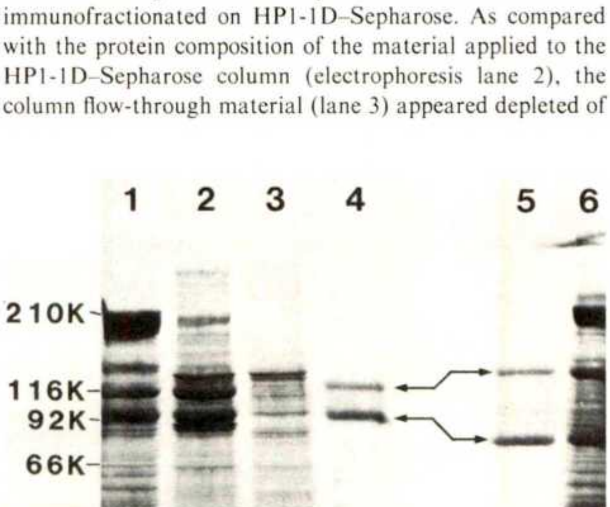

Fig 2. Polyacrylamide gel electrophoresis of immunofractionated platelet membrane proteins (Coomassie blue staining) demonstrating the specificity of HP1-1D monoclonal antibody for glycoproteins IIb and IIIa. Platelet membrane vesicles were detergent extracted and subjected to HP1-1D–Sepharose immunoaffinity chromatography. Fractions were treated with *N*-ethylmaleimide, solubilized with SDS (±β-mercaptoethanol), and subjected to 4% to 12% linear gradient polyacrylamide gel electrophoresis. The arrows between lanes 4 (reduced proteins) and 5 (nonreduced proteins) depict the electrophoretic mobilities of glycoproteins IIb and IIIa. Lanes: 1 to 4, samples reduced; 5 and 6, samples not reduced. 1, isolated platelet membranes (46 μg protein); 2, CHAPS-extracted platelet membranes (32 μg protein); 3, HP1-1D-Sepharose flow-through fraction (31 μg protein); 4, HP1-1D-Sepharose diethylamine eluate (16 μg protein); 5, HP1-1D–Sepharose diethylamine eluate (16 μg protein); and 6, isolated platelet membranes (46 μg protein).

Immunoaffinity isolation of megakaryocytic glycoproteins IIb and IIIa. Radiolabeled lysates of picked megakaryocytes were subjected to immunoaffinity chromatography as described in Materials and Methods. The lysates were prechromatographed on glycine-quenched Affigel and anti–HFX-Sepharose to decrease the amount of nonspecific binding by ^{35}S-labeled proteins to agarose. Half of the anti–HFX-Sepharose flow-through was incubated with HP1-1D–Sepharose and half with control anti–HAT III–Sepharose. Anti–HAT III–Sepharose was used as a control resin because the molecular weight of HAT III is substantially different from that of glycoproteins IIb and IIIa. Bound fractions were eluted as described in Materials and Methods, and pooled fractions were subjected to polyacrylamide gel electrophoresis and autoradiography.

Figure 3A shows the results of polyacrylamide gel electrophoresis of immunofractionated ^{35}S-labeled proteins synthesized by megakaryocytes from experiment 1. As expected, many proteins are synthesized by picked and pooled cultured megakaryocytes (lanes 1 and 13). Prechromatography on glycine-quenched Affigel and anti–HFX-Sepharose did not significantly change the megakaryocytic protein distribution (lanes 2, 3, and 8) present in the column flow-through fractions. However, two major proteins with apparent molecular weights of 116,000 and 101,000 (reduced) or 131,000 and 87,000 (nonreduced) are depleted from the HP1-1D–Sepharose flow-through (lanes 4 and 9) and are specifically released from HP1-1D–Sepharose by diethylamine (lanes 5 and 10). The apparent molecular weights (under both reducing and nonreducing conditions) of the ^{35}S-labeled megakaryocytic proteins specifically bound to and eluted from HP1-1D–Sepharose are essentially identical, within experimental error, with those of glycoproteins IIb and IIIa isolated from platelet membranes using similar conditions

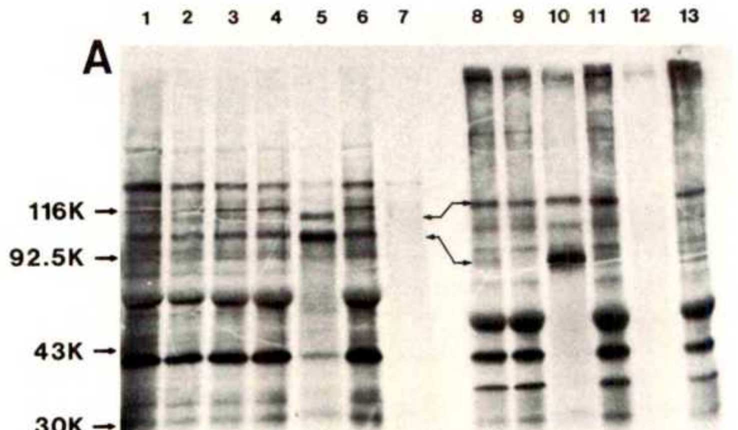

Fig 3. Polyacrylamide gel electrophoresis of immunofractionated ^{35}S-labeled proteins synthesized by human megakaryocytes and macrophages (autoradiogram) demonstrating the biosynthesis of glycoproteins IIb and IIIa by megakaryocytes. Metabolically radiolabeled megakaryocyte and macrophage proteins from experiment 1 (Table 1) were solubilized, chromatographed, and analyzed by 5% to 15% linear gradient polyacrylamide gel electrophoresis as described in Materials and Methods. (A) Picked and pooled megakaryocytes. (B) Picked and pooled macrophages. Lanes 1 to 7, samples are reduced; lanes 8 to 13, samples are not reduced. There are approximately 15,000 cpm/lane. The arrows between lanes 7 (reduced proteins) and 8 (nonreduced proteins) depict the electrophoretic mobilities of glycoproteins IIb and IIIa. Lanes: 1 and 13, solubilized cells and culture fluid; 2, Glycine-quenched Affigel flow-through; 3 and 8, anti-HFX-Sepharose flow-through; 4 and 9, HP1-1D (antiglycoprotein IIb/IIIa)-Sepharose flow-through; 5 and 10, HP1-1D-Sepharose diethylamine eluate; 6 and 11, anti-HAT III-Sepharose flow-through; and 7 and 12, anti-HAT III-Sepharose diethylamine eluate.

(Fig 2). Approximately 6.7% of the total counts per minute bound to HP1-1D–Sepharose and was eluted from the column.

Control anti–HAT III–Sepharose did not bind the two major proteins since they eluted in the flow-through fraction (lanes 6 and 11) and were not present in the diethylamine eluate (lanes 7 and 12). A protein of apparent molecular weight 42,000 under reducing conditions, probably actin, nonspecifically bound to both the HP1-1D–Sepharose and the anti–HAT III–Sepharose. This protein also nonspecifically bound to the prechromatography resins (data not shown). Under nonreducing conditions, a minor protein component with an apparent molecular weight of 105,000 was observed to bind to HP1-1D–Sepharose (lane 10). The identity of this protein is not known, but it is also a minor component of the nonreduced platelet membrane proteins that bound to and were eluted from HP1-1D–Sepharose (Fig 2, lane 5).

Since the picked and pooled megakaryocyte colonies contained a significant number of contaminating macrophages, it was important to fractionate the proteins synthesized by picked and pooled macrophages. Approximately 20,000 macrophages were treated in an identical fashion as the megakaryocytic population from the same donor. Figure 3B shows the results of polyacrylamide gel electrophoresis of immunofractionated ^{35}S-labeled proteins synthesized by the control macrophages from experiment 1. The picked and pooled macrophages were able to synthesize significant amounts of protein (Table 1 and Fig 3B, lanes 1 and 13). However, Fig 3B also shows that significant amounts of proteins with mobilities similar to glycoproteins IIb and IIIa were not synthesized by the macrophages, nor were such proteins bound by HP1-1D–Sepharose (lanes 5 and 10) or by anti–HAT III–Sepharose (lanes 7 and 12). This experiment shows that the amount of glycoproteins IIb and IIIa synthesized by the megakaryocytic population cannot be accounted for by the contaminant macrophages that were present in the megakaryocyte population.

Figure 4 shows that immunofractionation of ^{35}S-labeled proteins synthesized by megakaryocytes and macrophages from experiment 2 yielded essentially the same results as in experiment 1. Again, HP1-1D–Sepharose specifically bound

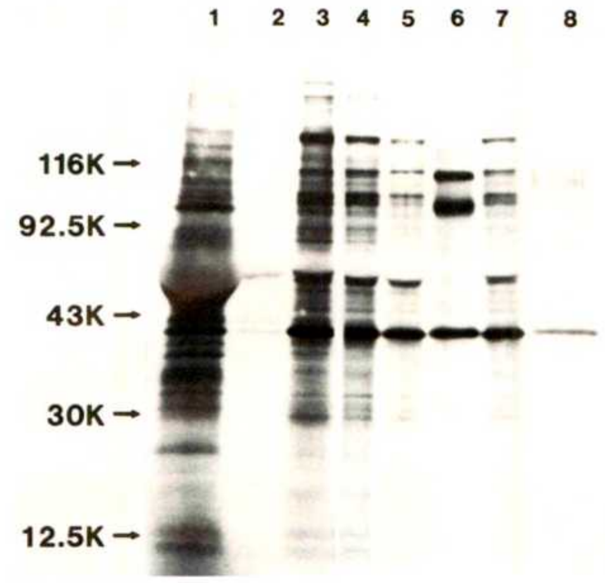

Fig 4. Polyacrylamide gel electrophoresis of immunofractionated ^{35}S-labeled proteins synthesized by human megakaryocytes and macrophages (autoradiogram), a second experiment demonstrating the biosynthesis of glycoproteins IIb and IIIa by megakaryocytes. Metabolically radiolabeled cell proteins from experiment 2 (Table 1) were solubilized, chromatographed, and analyzed by 5% to 15% linear gradient polyacrylamide gel electrophoresis as described in Materials and Methods. All samples are reduced. There are approximately 15,000 cpm/lane (except lane 2, 1,500 cpm). Lanes: 1, solubilized macrophages and culture fluid; 2, solubilized macrophages and culture fluid (1,500 cpm); 3, solubilized megakaryocytes and culture fluid; 4, megakaryocyte anti-HFX-Sepharose flow-through; 5, megakaryocyte HP1-1D-Sepharose flow-through; 6, megakaryocyte HP1-1D-Sepharose diethylamine eluate; 7, megakaryocyte anti-HAT III-Sepharose flow-through; and 8, megakaryocyte anti-HAT III-Sepharose diethylamine eluate.

and released two proteins synthesized by megakaryocytes that have apparent molecular weights (reduced) of 122,000 and 102,000 (lane 6), identical, within experimental error, to those of platelet glycoproteins IIb and IIIa. The proteins were present in the prechromatography lysate and in the anti-HFX-Sepharose flow-through (lanes 3 and 4). They were depleted in the HP1-1D-Sepharose flow-through (lane 5) and were released by diethylamine (lane 6). In experiment 2, approximately 6.1% of the applied counts per minute bound to the HP1-1D resin. Control anti-HAT III-Sepharose did not bind the two proteins since they eluted in the flow-through fraction and were not present in the diethylamine eluate (lanes 7 and 8). Again, a 42,000-dalton protein bound nonspecifically to both the HP1-1D-Sepharose and the anti-HAT III-Sepharose resins.

Approximately 15,000 macrophages from the same donor were also incubated with ^{35}S-methionine, and solubilized aliquots were electrophoresed. A volume of lysed macrophages, equivalent to the volume of lysed megakarayocytes, was electrophoresed in lane 2. No significant amount of labeled protein is seen in this sample. When tenfold more sample was electrophoresed (lane 1), many newly synthesized proteins were observed upon electrophoresis, but no intense bands were seen with mobilities similar to glycoproteins IIb and IIIa. This confirmed that the amount of glycoproteins IIb and IIIa synthesized by the megakaryocytic population in experiment 2 could not be accounted for by the number of contaminating macrophages in that population.

DISCUSSION

Our results show that protein synthesis in normal human megakaryocytes can be studied by picking and pooling CFU-M-derived megakaryocytic colonies grown in vitro. We elected to study first the synthesis of glycoproteins IIb and IIIa because of the relatively well-characterized role these proteins play in platelet hemostatic function[20,21] and because other laboratories and our own[12,13,22-24] have shown that glycoproteins IIb and IIIa are among the first proteins detected by indirect immunofluorescent techniques in the earliest stages of megakaryocytic differentiation.

We demonstrate that approximately 100,000 human megakaryocytes of 70% to 90% purity can be reliably obtained by picking and pooling CFU-M-derived megakaryocytic colonies. Other investigators have studied megakaryocytes enriched from human or nonhuman bone marrow with techniques including density gradient centrifugation and velocity sedimentation or centrifugal elutriation.[1-5,8,22,25] Both cell sorting[26,27] and panning techniques[28] have also been used to enrich marrow megakaryocytes. All of these methods either are time consuming or require relatively large amounts of bone marrow, for example, from human ribs, to obtain a significant number of megakaryocytes. Although CFU-M-derived megakaryocytes require 2 weeks of culture, only a small amount of bone marrow aspirate (2 to 3 mL) is required as starting material. In addition, when bone marrow aspiration is not clinically or technically feasible, peripheral blood mononuclear cells can serve as a source of CFU-M-derived megakaryocytes.[29] Thus, it is possible to study protein synthesis in CFU-M-derived megakaryocytes from patients with inherited or acquired disorders of platelet proteins. Our work also shows that enriched populations of other cell types, such as macrophages, can be obtained for use as control cell suspensions for synthetic studies.

Our data confirm that the murine monoclonal antibody HP1-1D reacts with the human platelet membrane glycoprotein IIb/IIIa complex.[13-15] Furthermore, HP1-1D antibody coupled to Sepharose can be used to purify platelet glycoproteins IIb and IIIa, which have appropriate nonreduced and reduced electrophoretic mobilities in polyacrylamide gels.[19] Recent studies[21] suggest that platelet membrane glycoproteins IIb and IIIa exist as calcium-dependent, noncovalently linked heterodimer complexes and that this association may be required for expression of the functional properties of the proteins. Although HP1-1D antibody is specific for glycoprotein IIb/IIIa antigen and can be used to isolate the two proteins, our studies reported here do not allow us to clearly determine whether HP1-1D antibody has specificity for a heterodimer-dependent epitope of glycoprotein IIb/IIIa or whether the epitope is present on only one of the proteins, both of which remain associated in detergent-solubilized cell preparations and coisolate using HP1-1D-Sepharose.

We find that cultured human megakaryocytes synthesize two ^{35}S-labeled proteins that are specifically bound to and released from HP1-1D–Sepharose. Similar ^{35}S-labeled proteins are not specifically bound by control anti–HAT III–Sepharose. The two synthesized proteins specifically bound by HP1-1D–Sepharose have reduced and nonreduced electrophoretic mobilities in polyacrylamide gels identical with those of platelet glycoproteins IIb and IIIa.

Our experiments do not eliminate the possibility that macrophages may synthesize small amounts of glycoproteins IIb and IIIa. However, the experiments do show that the number of macrophages contaminating the pooled megakaryocytes do not synthesize a detectable amount of glycoproteins IIb and IIIa.

The pooled megakaryocytes derived from picked megakaryocytic colonies contain cells in all stages of the megakaryocytic lineage,[12] from small, round, lymphoid-appearing cells to large megakaryocytes. Our data reported here do not allow us to make inferences about the relative synthetic capacities of early or late megakaryocytes. However, we are now subfractionating the picked and pooled megakaryocytic population to study the synthesis of proteins by cells of different size and cell surface properties.

ACKNOWLEDGMENT

We thank Scott Kaese and Karl Oles for technical assistance and Dorothy Suddendorf, Sandra Schumann, and Carolyn Johnston for secretarial assistance. We also appreciate Dr Hans Messner and Nazir Jamal teaching us the in vitro culture technique.

Clinical and Laboratory Characteristics of Acute Leukemia with the 4;11 Translocation

By Joseph Mirro, Geoffrey Kitchingman, Dorothy Williams, Gilles J. Lauzon, Chyi-Chyang Lin, Thomas Callihan, and Theodore F. Zipf

This report describes the clinical and laboratory features of seven cases of acute leukemia associated with the 4;11 chromosomal translocation. All seven children had acute lymphoblastic leukemia by standard morphologic and cytochemical criteria. Leukemic blasts from six of seven patients were terminal deoxynucleotidyl transferase-positive. Immunologic phenotyping suggested the leukemias were of B cell origin; blasts from five patients expressed HLA-DR and p24 (CD-9 antibody), blasts from three patients expressed B4 (CD-19), and blasts from two patients expressed the common acute lymphoblastic leukemia antigen (CD-10). One patient's leukemic blasts contained cytoplasmic immunoglobulin. Analysis of DNA from four of five patients demonstrated additional evidence of B cell differentiation with heavy-chain immunoglobulin gene rearrangement. When DNA from the four patients with heavy-chain immunoglobulin gene rearrangement was analyzed, one patient's DNA demonstrated light-chain immunoglobulin gene rearrangement. However, flow cytometric analysis of blasts from three patients showed the simultaneous expression of the lymphoid-associated antigen B4 (CD-19) and the myeloid-associated antigen My-1 (X-Hapten). Electron microscopic examination of blasts from one patient that expressed both lymphoid- and myeloid-associated antigens demonstrated ultrastructural characteristics of both lineages. These findings suggest that acute leukemia with the t(4;11) abnormality has mixed lineage characteristics as a result of leukemogenesis in a multipotential progenitor cell or aberrant gene expression later in differentiation. Furthermore, serial analysis of karyotype, immunophenotype, and heavy-chain immunoglobulin genes revealed changes in these biologic markers over time, suggesting continued chromosome rearrangement and gene modulation after the leukemogenic event in cells with the t(4;11).

© 1986 by Grune & Stratton, Inc.

THE ASSOCIATION of the chromosomal translocation t(4;11) with acute leukemia characterized by hyperleukocytosis, a young age, and a poor prognosis has been described.[1-4] This translocation was first reported to be associated with acute lymphocytic leukemia (ALL). Further studies have suggested that the leukemogenic process involves either (1) a precursor cell with the capacity to differentiate along either myeloid or lymphoid lineages or (2) a myeloid progenitor cell.[5,6] We, therefore, analyzed the clinical and laboratory characteristics of seven patients with the t(4;11) in an effort to clarify the lineage of this abnormality. Our studies indicate that this translocation is usually associated with a lymphoid morphology and heavy-chain immunoglobulin gene rearrangement. Although the majority of blasts expressed lymphoid-associated surface antigens, careful flow cytometric analysis of cell surface antigens demonstrated the simultaneous expression of lymphoid- and myeloid-associated antigens on individual blasts from all three patients studied. Ultrastructural study in one patient confirmed dual lineage characteristics within individual leukemic cells. The expression of mixed lineage characteristics[7-11] supports the idea that either a multipotential precursor cell is involved[5,12,13] or aberrant gene expression occurs in leukemias with t(4;11).[14] Our findings are consistent with the descriptions of this translocation in both lymphoid[4] and myeloid[5,6] leukemia and in a cell line with characteristics of both lineages.[15] Furthermore, serial studies of karyotypes, immunophenotypes, and heavy-chain immunoglobulin gene rearrangements at diagnosis and relapse in our patients suggests that such biologic characteristics undergo modification in leukemic cells with this translocation.

MATERIALS AND METHODS

Patients. From Sept 1979 to Feb 1984, 329 of 413 newly diagnosed children with acute leukemia seen at St Jude Children's Research Hospital had adequate mitoses for bone marrow chromosome analysis. Six of these patients were found to have the t(4;11). From Oct 1981 to Oct 1983, 11 of 12 newly diagnosed children with acute leukemia seen at the Tom Baker Cancer Centre had adequate mitoses for bone marrow chromosome analysis, and patient 7 is from that institution. None of the patients in this series had a history of hematologic disorders. All patients were treated with modern, intensive, combination chemotherapy and CNS prophylactic therapy.[16-18] The blasts of all patients were included in leukemia cell profile studies approved by the institutions' clinical trials committees. Informed consent was obtained in each instance.

Morphologic and cytochemical studies. Bone marrow smears were stained with Wright-Giemsa, periodic-acid Schiff (PAS), myeloperoxidase (MPO), Sudan black B (SBB), chloroacetate esterase (CAE), and alphanapthyl butyrate (ANB).[19] Morphologic classification followed conventions of the French-American-British (FAB) cooperative group.[20]

Ultrastructural study. Electron microscopic studies were performed on previously frozen bone marrow cells from patient 7. Ultrastructural localization of peroxidase was performed by the method of Breton-Gorius et al.[21] The cryoprotectant was removed by washing, and the cells were fixed for one hour at 4 °C in 0.5% glutaraldehyde with 2% paraformaldehyde and 1% tannic acid. After washing, the cells were incubated in the dark at room temperature in diaminobenzidine/hydrogen peroxide for one hour.

The cells were postfixed in 1% osmic acid, dehydrated in increasing concentrations of ethanol, and embedded in Spurr. Unstained grids and grids stained with uranyl acetate and lead citrate were examined.

Chromosome analysis. Bone marrow cells were obtained from heparinized posterior iliac crest aspirates and were processed within 30 minutes of aspiration. Direct preparations were done in all instances, and in some cases they were supplemented by 24-hour unstimulated cultures. Early studies were performed with a modification of the technique of Tjio and Whang.[22] More recently cases were studied with a direct bone marrow technique that includes treatment with trypsin and staining with Wright's stain to obtain G-banding.[23]

Immunophenotyping and terminal transferase assay. Leukemic blasts were studied for rosette formation with sheep erythrocytes at 37 °C, and the results were considered positive if rosette formation was noted for >3% of blasts (confirmed on cytocentrifuge preparations). Bone marrow samples containing >80% leukemic cells were analyzed with a standard indirect immunofluorescence assay using monoclonal antibodies (MoAb) to identify cell surface antigens. Cells were first incubated in heat-inactivated, pooled human AB serum to eliminate Fc binding. Cells incubated with isotypic myeloma immunoglobulin (Litton-Bionetics, Charleston, SC) at a concentration equal to the least diluted MoAb were used as negative controls. Lymphoid-associated antigens were identified with multiple antibodies representative of the cluster groups (CD) identified at the First or Second International Workshops on Leukocyte Differentiation Antigens and included p24 (CD-9),[24] common acute lymphoblastic leukemia antigen (CALLA) (CD-10),[25] B4 (CD-19),[26] T-11 (CD-2),[27] and T101 (CD-5).[28] The HLA-DR antigen was detected by MoAb L243.[29] When adequate cells were available, the presence of myeloid-associated surface antigens was assessed by a panel of markers including My-1,[30] Mo1 (CD-11),[31] SJ-D1 (provisional cluster, CDw14),[32] 5F1 (CDw14), and T5A7 (CDw17).[33] Immunophenotyping also included an analysis for surface (sIg) and cytoplasmic (cIg) immunoglobulins. Terminal deoxynucleotidyl transferase (TdT) was identified by use of an indirect immunofluorescence assay.[34]

Dual beam cytometric flow analysis. Two-color immunofluorescence measurements were carried out on a modified System 50H Cytofluorograf (Ortho Diagnostics, Westwood, Mass) equipped with an argon ion laser (model 164-05, Spectra Physics, Mountain View, Calif) and a tunable dye laser (model 590, Coherent, Palo Alto, Calif). The dye laser was pumped by an argon ion laser (Innova 90/5, Coherent) operating at 514 nm with an output power of 1 W. The argon ion laser operating at 488 nm (400 mW) excited fluorescein isothiocyanate conjugated (FITC) probes, whereas the dye laser was tuned to 590 nm (280 mW) for the excitation of Texas Red (TR) conjugated probes. The green (FITC) detection channel contained two bandpass (BP) filters in series: a 515-530 BP (Ortho) and a 515-525 BP (Oriel Corp, Stamford, Conn). A 625-635 BP filter (Becton Dickinson, Sunnyvale, Calif) was placed in the red detection channel. This combination of filters, in addition to the spatial separation of the images from the two beams, resulted in the complete absence of light from one fluorochrome at the detector for the other. Data was recorded and analyzed on a model 2150 computer (Ortho).

Indirect immunofluorescence was used for the determination of the presence of cell surface antigen by MoAb binding. All MoAbs were purified either by affinity or protein A–sepharose chromatography. The saturating concentration of MoAb was selected as described previously.[35] FITC goat antimouse μ- or γ-chain–specific antibodies (Cappel Laboratories, Cochranville, Pa) were used as the second-stage reagent for the green detection channel. Biotinylated MoAbs were used for analysis using the red channel, with the second-stage reagent being TR-conjugated avidin (Tago Inc, Burlingame, Calif). The application of the biotinylated antibody always followed incubation with the FITC goat antimouse step.

Two-color immunofluorescence experiments were repeated, with each primary MoAb being detected by the alternate second-stage fluorochrome to assess the consistency of the measurements. These experiments, of necessity, required that the primary MoAbs be applied in reverse order. Isotype- or subtype-identical mouse myeloma proteins were used as controls at concentrations identical to the primary MoAb as determined by an enzyme-linked immunosorbent assay. Two-dimensional arrays were then constructed using an algorithm that computed the expected number of cells in each element resulting from nonspecific binding. The array corresponding to the appropriate control antibodies was then subtracted from the array for the test antibody.

Immunoglobulin gene analysis. For each patient, 20 μg of leukemic cell DNA was digested with the appropriate enzyme *Bam*HI, *Hind*III, or *Eco*RI (3 U/μg DNA; Amersham Corp, Arlington Heights, Ill). The digested DNA was fractionated by electrophoresis on a 0.8% agarose gel, transferred to nitrocellulose paper according to the technique of Southern,[36] and hybridized with nick-translated probes with specific activities of 2 to 5 × 10^8 cpm/μg DNA. The heavy-chain immunoglobulin gene probes included a 1.2 kb *Eco*RI fragment representing portions of the $C\mu 1$ and $C\mu 3$ domains and all of the $C\mu 2$ domain[37] or a 3.4 kb *Hind*III/*Eco*RI fragment of the J_H region.[38] A 2.5 kb germ line *Eco*RI fragment was used to analyze the κ light-chain gene, and an 8.0 kb *Eco*RI fragment

used to analyze the λ light-chain gene.[39] After high-stringency conditions were used for hybridization and washing, the filters were washed, dried, and exposed at −70 °C to XAR-5 films (Kodak, Rochester, NY) for one to five days in the presence of intensifying screens. All experiments included control DNA from normal mononuclear cells, tonsil or spleen.

RESULTS

Incidence. Of the 340 children with acute leukemia for whom chromosome analyses were performed, 237 had complete banding. The 4;11 translocation was identified in leukemic cells from six of these patients at diagnosis, indicating that the incidence of this abnormality in childhood acute leukemia is at least 2.5%.

Laboratory findings. Table 1 presents the clinical data on all seven children. The median age was 3.7 years (range, 0.3 to 14 years). Five children were female, and two were male. Three children (nos. 1, 6, and 7) had massive hepatosplenomegaly at diagnosis. The four patients (nos. 1, 4, 6, and 7) with extreme leukocytosis (median, 310 × 10^9/L; range, 210 to 346 × 10^9/L) had only the t(4;11) karyotypic abnormality detected at diagnosis (Table 2). The three patients (nos. 2, 3, and 5) with distinctly lower leukocyte counts (median, 27.3 × 10^9/L; range, 12.1 to 27.8 × 10^9/L) had associated karyotypic abnormalities and may represent a clinically distinct subgroup of patients with t(4;11). The hemoglobin concentrations (range, 2.3 to 11.7 g/dL) and platelet counts (range, 10 to 159 × 10^9/L) were variable in these patients. Three patients (nos. 1, 2, and 7) had overt CNS disease with leukemic cells in their spinal fluid. No patient had a mediastinal mass, and only one had significant adenopathy. By light microscopic examination, the leukemic blasts from all seven patients were morphologically lymphoid (FAB L1 or L2) without MPO, SBB, CAE, or ANB staining.

Six of the seven children demonstrated the t(4;11)(q21;q23) chromosomal rearrangement at the time of diagnosis, whereas patient 2 exhibited this abnormality only at relapse (Table 2). In patient 1 the t(4;11) was not detected at relapse, but patients 4 and 7 demonstrated this abnormality at both diagnosis and relapse. Three out of 4 patients had different karyotypes at relapse, and patient 2 had karyotypic changes between diagnosis, the first, and the second hematologic relapse. In four of the seven patients, the t(4;11) was associated with other chromosomal abnormalities either at diagnosis (patients 3 and 5) or at relapse (patients 2 and 4). No patient demonstrated an extra chromosome number 14 at diagnosis or at relapse.

The results of immunophenotyping and TdT analysis are presented in Table 3. A large percentage (range, 60% to 98%) of leukemic blasts from five of the six patients tested expressed TdT activity at the time of diagnosis. Blasts from all six children that could be studied at diagnosis expressed

*Positive when tested by flow cytometry (see text).

All results given as percent positive cells determined by fluorescence microscopy.

HLA-DR, whereas four expressed p24 (CD-9). No blasts formed E rosettes or reacted with anti–T cell MoAbs. Blasts from patient 4 contained cIg at diagnosis and relapse, whereas the blasts from patient 2 expressed CALLA (CD-10) at diagnosis but not at the first or second hematological relapse. All three patients tested (nos. 4, 6, and 7) expressed the B lineage–associated surface antigen B4 (CD-19).

Cells taken at diagnosis from four patients were examined for the presence of myeloid-associated antigens. Two of these four (nos. 4 and 7) showed definite positive subpopulations (>15%). Patients 4 and 7 with My-1$^+$ blasts have relapsed and their blasts again expressed this antigen. Blasts from patient 2 were not tested at diagnosis but were My-1$^+$ at the first and second relapse. There were adequate cells remaining from the diagnostic specimens of three patients (nos. 4, 6, and 7) to allow detailed studies using flow cytometry. Using single-fluorochrome analysis, histograms demonstrated definite My-1 (X-Hapten) and T5A7 (CDw17)-positive subpopulations when compared with cells incubated with the control myeloma protein, and the ratio of My-1$^+$ cells to My-1$^+$ cells was always greater than unity (range, 1.1 to 2.3). The majority of the blasts from these three patients were also positive for the pan–B cell antigen B4 (≥85%). Dual beam immunofluorescence was then used to demonstrate that

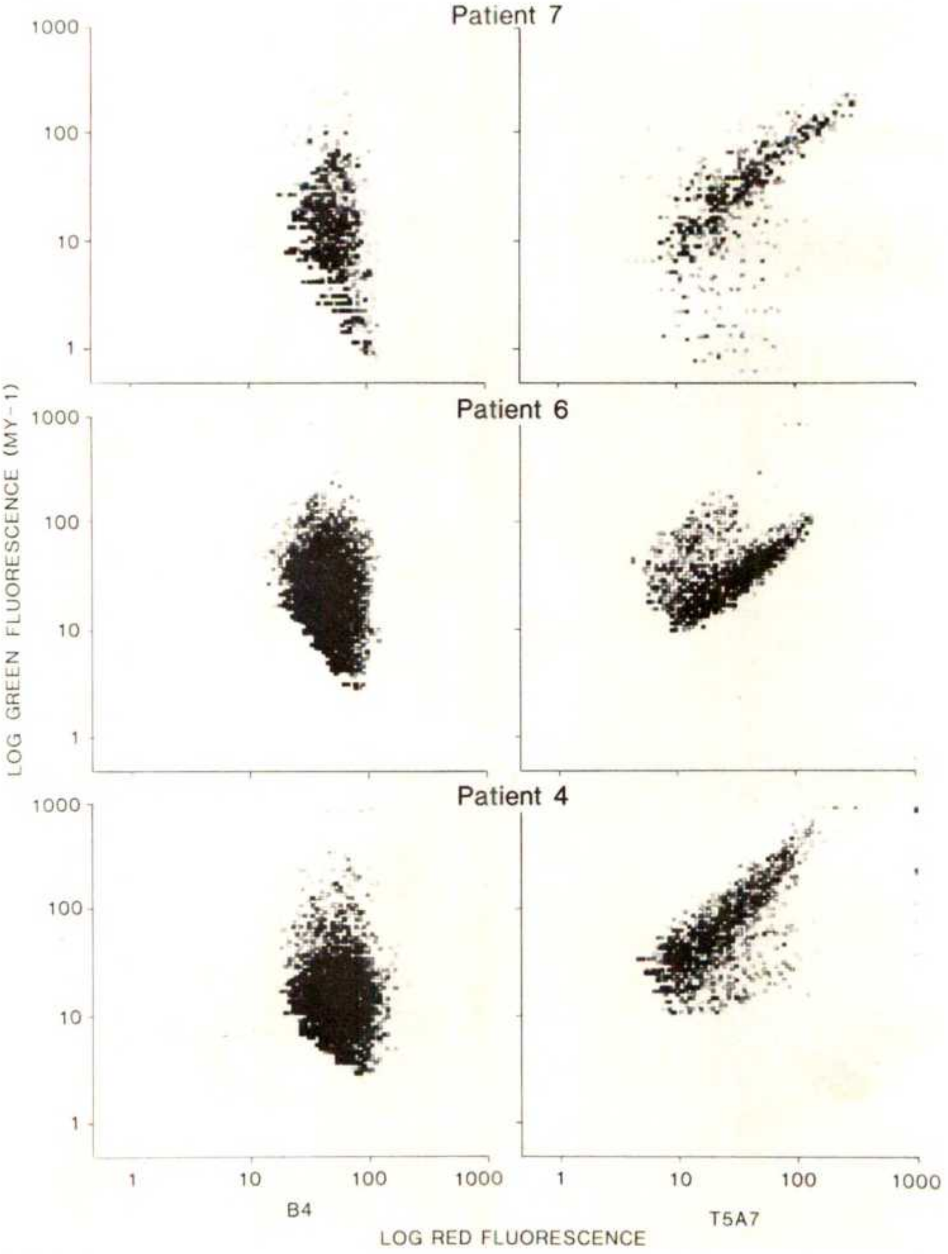

Fig 1. Results of the dual-beam immunofluorescence measurements on the My-1$^+$ blasts. The data shown here are the resultant distributions of double-labeled cells after the background resulting from nonspecific binding was subtracted. Log green fluorescence, My-1 binding, is shown on the y-axis, and Log red fluorescence, B4 or T5A7 binding, is shown on the x-axis. In all three patients (nos. 4, 6, and 7) the number of My-1$^+$ cells was equal to the number of My-1$^+$, B4+ cells and less than 10% of the My-1$^+$ cells did not bind MoAb T5A7.

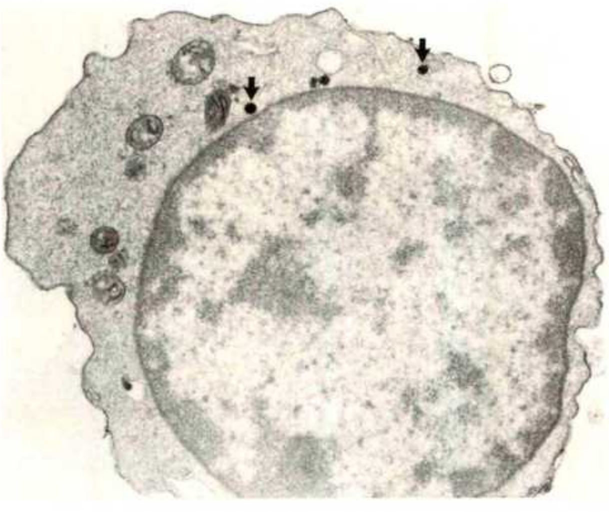

Fig 2. Electron microscopic features of leukemic blasts from patient 7. A leukemic blast with lymphoid morphology demonstrates several peroxidase-positive granules (arrows). (Original magnification ×25,475; current magnification ×9,171.)

virtually all My-1 + cells expressed B4 and greater than 90% of the My-1^{+} cells were also T5A7+ (Fig 1). The B4-positive cells also simultaneously expressed the p24 (CD-9) and HLA-DR antigens (data not shown). In the two-color experiments, the use of alternate fluorochromes, as explained in Materials and Methods, did not affect the results.

Ultrastructural studies on patient 7 were consistent with the dual-beam immunofluorescence studies. The predominant blasts appeared lymphoid with a round-to-ovoid nucleus, peripherally marginated chromatin, and one or two prominent nucleoli. The cytoplasm contained variable numbers of mitochondria, occasional short strands of rough endoplasmic reticulum, and polyribosomes. Approximately 25% of these lymphoid-appearing blasts contained electron-dense, membrane-bound granules that were peroxidase-positive (Fig 2). In addition, there was a population of blasts that was monocytoid, comprising approximately 15% to 20% of the blast cell population. These cells were larger than the lymphoid-appearing blasts and contained nuclei that were infolded with evenly distributed chromatin and a prominent nucleolus. In these cells the cytoplasm was more abundant and contained an occasional Golgi apparatus as well as numerous small electron-dense granules, some of which were peroxidase positive. Extensive examination of multiple grids failed to reveal a population of cells that exhibited dysplastic myeloid features or contained basophil/mast cell granules.

Four of five patients tested at diagnosis (nos. 1, 2, 4, and 6) showed evidence of heavy-chain immunoglobulin gene rearrangement (Table 4). Patient 6 had only a single rearranged μ gene, whereas three of these patients (nos. 1, 2, and 4) demonstrated more than two bands that hybridized to the μ constant-region probe. When the results were analyzed using a densitometer, the DNA from patient 1 had three bands (one germ line, two rearranged), and the DNA from patient 4 had at least four bands (one germ line, three rearranged) that hybridized to the Cμ probe after *Bam*HI digestion (Fig 3). Patient 2 demonstrated distinct differences in karyotype and immunophenotype between diagnosis and each relapse (Tables 2 and 3). This patient also demonstrated distinct changes in the sizes of the μ-chain gene rearrangements. When analyzed by *Bam*HI digestion, four μ constant-region–hybridizing bands were present at diagnosis, but at first hematologic relapse only three were present (Fig 3). Analysis of the DNA from patient 2 at the time of first relapse by *Hind*III digestion and J_H probing revealed a far more complex pattern than that seen by *Bam*HI digestion, with ten bands being apparent on the autoradiogram (Fig 4). Of these, 9 are rearranged and 1 is germ line. This pattern is reproducible and probably does not represent underdigestion of DNA. When DNA from the second relapse was examined by *Hind*III digestion and J_H probing, a much simpler pattern appeared, with three rearranged and one germ line μ genes being observed (Fig 4). It is clear that two of the rearranged bands represent the majority of the J_H-hybridizing material in this sample. The simultaneous analysis of the first and second relapse on the same gel clearly demonstrates conservation of some rearranged heavy-chain bands but the elimination of others. Analysis of DNA from patient 4 at the time of diagnosis using *Hind*III digestion and J_H probing also revealed a far more complex pattern than that seen using

*Several alleles are present, and one is rearranged.

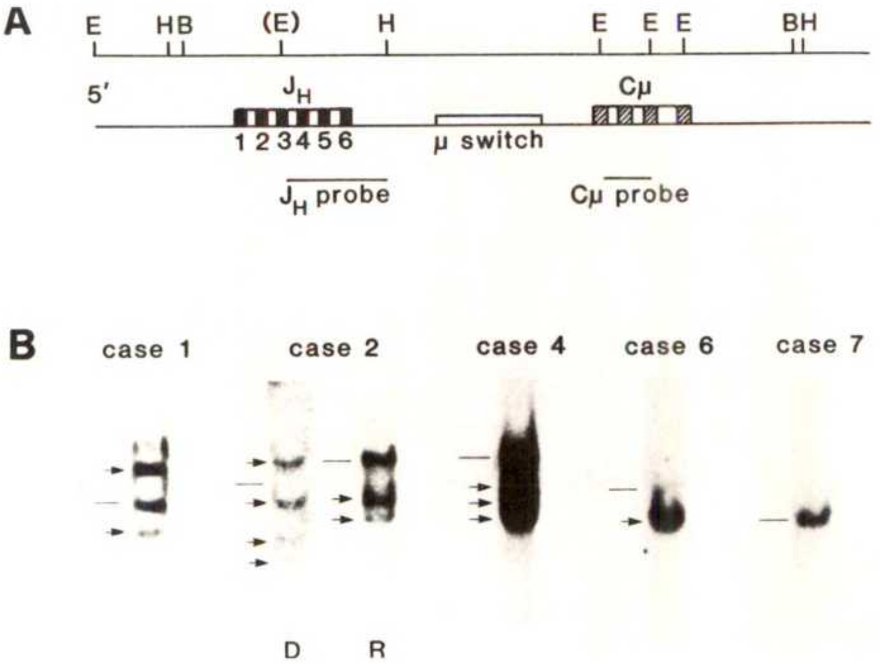

Fig 3. (A) Schematic representation of the human Ig gene region with restriction endonuclease sites: E, *Eco*RI; H, *Hind*III; and B, *Bam*HI. The Cμ probe consisted of a 1.2-kb *Eco*RI fragment subcloned into pACYC184 and contains the complete Cμ 2 domain and portions of Cμ 1 and Cμ 3. The J_H probe consisted of a 3.3-kb *Bam*HI/*Eco*RI fragment subcloned into pBR322. (B) Southern blot analysis of the Ig gene. DNA was digested with *Bam*HI, and blots were hybridized with a Cμ-specific probe. The results for cases 1, 2, (D, diagnosis; R, 1st relapse), 4, 6, and 7 are shown (lanes 1 to 6, respectively). Lines represent the positions of the 17-kb germ line gene in the gels. Arrows indicate the positions of rearranged bands (determined by densitometer).

*Bam*HI. The multiple-μ gene–hybridizing bands are clearly evident using *Hind*III digestion (Fig 4). Possible origins of the multiple bands will be discussed later.

Southern blots were washed to remove bound μ probe and rehybridized to a κ light-chain constant-region probe. None of the four patients with heavy-chain rearrangements had a rearranged κ light-chain gene (Table 4). The arrangement of the λ light-chain genes was examined using *Eco*RI digests, and one patient (no. 6) was found to have a λ light-chain gene allele rearranged. This was of interest since the κ-chain genes were apparently in the germ line configuration and κ-chain genes rearrange before λ in the Ig gene hierarchy.[40,41] Close examination of the κ-gene blot for this patient revealed that the intensity of hybridization was lower than the control DNA, indicating that perhaps one κ allele was deleted, although the second was in the germ line configuration. We conclude that, as found in several patients by Korsmeyer et al,[42] one κ-gene allele has been deleted and the rearrangement of the λ allele therefore does not violate the hierarchy of gene rearrangements.

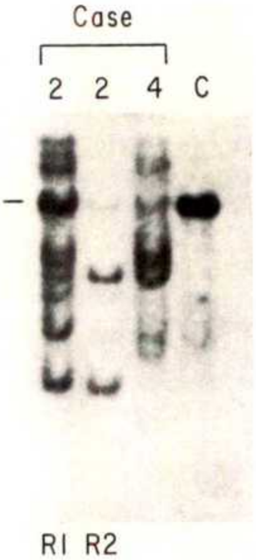

Fig 4. Southern blot analysis of the Ig gene for cases 2 and 4. DNA was digested with *Hind*III, and blots were hybridized with the J_H probe. The results for case 2 (R1, first relapse; R2, second relapse), case 4 (diagnosis), and the normal control are shown respectively in lanes 1 to 4. A line represents the position of the germ line gene.

Treatment outcome. All patients achieved complete remissions that ranged from 4+ to 30 months in duration. Patients 3, 5, and 6 remain in their first clinical remission 22+, 4+, and 4+ months, respectively. Patient 2 had a first remission that lasted 24 months and a second remission that lasted 12 months. The three patients in this report who died from progressive leukemia had survivals of 12, 14, and 41 months. Three of the four patients in whom a hematologic relapse developed achieved a second complete remission without difficulty.

DISCUSSION

We studied seven patients whose leukemic blasts had translocations between the long arms of chromosomes 4 and 11. Their ages ranged widely, and in contrast to several earlier reports,[5,6] their leukemic blast cells were clearly FAB-type L1 or L2. Only four patients had extreme hyperleukocytosis, a common finding in most series. Anemia and hepatosplenomegaly were not consistent features in our patients, and none presented with a mediastinal mass.

The majority of t(4;11)-positive patients reported in the literature achieved complete remissions; however, their remission lengths have seldom exceeded 8 months.[4-6] Whether the extended periods of complete remission in three of our patients reflect differences in other biologic characteristics or the use of more intensive therapy cannot be answered with certainty because of the small number of patients with the t(4;11).

The presence of associated karyotypic abnormalities in our patients is unusual and may be associated with important clinical characteristics such as a lower-median leukocyte count. The associated cytogenetic abnormality in patient 5 is particularly interesting since the inversion of chromosome 16 (p13q22) has been associated with nonlymphocytic leukemia.[43] The blast cells of three of four patients analyzed both at diagnosis and relapse showed karyotypic evolution, consistent with a previous report suggesting that karyotypic evolution may be common in patients with the t(4;11).[4] Not unexpectedly, we were able to show gene rearrangement and immunophenotypic evolution coincident with the observed chromosomal changes.

For the three cases in which adequate cells were available to allow extensive studies of surface antigen expression, greater than 85% of the blasts were positive for the pan–B cell antigen B4 (CD-19). This antigen is expressed early in B cell differentiation and is restricted to cells of the B lineage.[26] Subpopulations of B4$^+$ cells that expressed the p24 epitope (CD-9) also expressed the antigens identified by the MoAbs My-1 and T5A7. The molecule bearing the p24 epitope has been found on the surface of non-T, non-B ALL blasts and platelets as well as cells of monocytoid and lymphoid lineages.[24,44] MoAb My-1 detects a determinant (X-Hapten) expressed on the majority of myeloid cells and a subset of monocytes.[30,45] The reactivity of this MoAb appears to be restricted to nonlymphoid cells. The T5A7 MoAb is reactive with a lactosylceramide moiety that is the common precursor for glycosphingolipids of the lactoseries, ganglioseries, and globoseries.[46] This antibody has been shown to bind to cells of the myeloid lineage, monocytes, phytohemagglutinin-stimulated lymphocytes,[45,46] and approximately one third of non-T, non-B ALL blasts.[47] In three patients, we demonstrated simultaneous expression of a B lymphoid antigen (B4) (and several lymphoid-associated antigens) with a nonlymphoid antigen (My-1). These patients appear to have acute mixed-lineage leukemia (AMLL),[11] a finding consistent with reports of the t(4;11) in leukemic cells with lymphoid and myeloid characteristics.[4-6] A recent review of cases of hybrid acute leukemia suggested that simultaneous expression of myeloid and lymphoid characteristics may be associated with the t(4;11).[48] Of the 18 cases included in this review as hybrid leukemia, seven contained the t(4;11). Additionally, a recently described cell line containing the t(4;11) has both myeloid and lymphoid features,[15] similar to the cases we describe here.

The ultrastructural and ultracytochemical analysis of blast cells from patient 7 demonstrated both lymphoid and nonlymphoid characteristics. Thus, in this patient there appears to be a morphologic correlation with the immunologic identification of both lymphoid and nonlymphoid antigens on the same blasts. The ultrastructural features of this patient are similar to some of the previously described patients with acute leukemia characterized by the t(4;11) translocation.[5] In the series reported by Parkin et al,[5] blasts from eight of the ten patients exhibited predominantly lymphoid morphology. However, in one of the three patients tested, the lymphoid-appearing blasts contained peroxidase-positive granules.

Blasts from three of the five patients analyzed for immunoglobulin gene configuration demonstrated only heavy-chain rearrangements, whereas a fourth demonstrated both heavy- and light-chain gene rearrangements, suggesting a normal progression of B cell differentiation.[41,42,49] Although the finding of rearranged heavy-chain genes is not specific for leukemia of lymphoid lineage,[50] it is strongly B cell associated and provides indirect evidence for a lymphoid differentiation of the leukemic blasts.[41,42]

It is unusual and potentially important that three of the five patients we tested (nos. 1, 2, and 4) had greater than two DNA bands hybridizing with the immunoglobulin heavy-chain gene probe (Table 4, Figs 3 and 4). The presence of more than two rearranged μ-chain genes has been observed in transformed lymphoid cells[51] and in other leukemia patients.[52] More than two hybridizing bands could have resulted from additional alleles of the μ gene on extra copies of chromosome 14; however, we could not identify an extra chromosome 14 in any of our patients. Alternatively, multiple bands could result from more than one transformed clone, and therefore, such cases may represent biclonal leukemia.[53] A third explanation is that multiple bands are a result of evolution within the leukemic cell population. This hypothesis is supported by the finding of karyotypic evolution at relapse in the three patients having more than two heavy-chain immunoglobulin gene bands (Table 2). Further support for evolution in the leukemic population comes from our findings of coincident changes in karyotype, immunophenotype, and the heavy-chain immunoglobulin gene rearrangement at diagnosis and at relapse in one patient (no. 2). The pattern of rearrangements in patient 2 at first relapse (nine rearranged, one germ line) suggests the presence of five distinct sublines (Fig 4). This is reminiscent of the continued rearrangement of Ig heavy-chain genes that occurs in Abelson murine leukemia virus–transformed cells in which up to six sublines have been observed to arise from a clonal population over several months in culture.[54] A relationship between the evolution of biologic characteristics and relapse is purely speculative, but provocative. If such a relationship exists, it will be clarified by larger studies.[52]

In each of our cases, the break point on chromosome 11 was within or near bands q23–q24. Recent localization of the c-*ets* oncogene on chromosome 11 at this position suggests that c-*ets* could be involved in the pathogenesis of some cases of acute leukemia.[55] It will be interesting to examine t(4;11)-positive blasts for activation of the c-*ets* oncogene, which may be important for leukemogenesis.

ACKNOWLEDGMENT

We thank L. Woodruff, L. Bryant, and V. Denison for excellent technical assistance, Drs C. Civin, J. Kersey, L. Nadler, and I. Bernstein for their gifts of monoclonal antibodies, and Drs T. Rabbitts, P. Leder, and C. Croce for their gift of Ig gene probes. We also thank J. Gilbert and M. Zipf for editorial assistance, Dr S.B. Murphy for advice and support, and G.N. Koskowich for computer programming and assistance with flow cytometry.

Biologic and Prognostic Significance of the Presence of More Than Two μ Heavy-Chain Genes in Childhood Acute Lymphoblastic Leukemia of B Precursor Cell Origin

By Geoffrey R. Kitchingman, Joseph Mirro, Sanford Stass, Ugo Rovigatti, Susan L. Melvin, Dorothy L. Williams, Susana C. Raimondi, and Sharon B. Murphy

We examined the arrangement of the μ heavy-chain immunoglobulin (Ig) genes in the leukemic blast cell DNA of 93 children with acute lymphoblastic leukemia (ALL). All cases met morphologic and cytochemical criteria for ALL, lacked detectable T cell surface antigens, and expressed HLA-DR (Ia) antigens. Eighty-three of the 93 patients (89%) were positive for the common acute lymphoblastic leukemia antigen (CALLA), and 20 of 91 (22%) tested had detectable cytoplasmic immunoglobulin. As expected, the heavy-chain Ig gene was rearranged in all cases, and the pattern of rearrangements was variable; 23 had one allele rearranged and one in the germ line configuration; 15 had one rearranged and one deleted; and 37 had two rearranged. Unexpectedly, in 18 patients the presence of more than two μ gene-hybridizing bands was detected. Combinations of enzymes and heavy-chain gene probes were used to confirm that the extra bands were not the result of underdigestion of the DNA or DNA restriction site polymorphism. In eight of the 18 patients, we identified an extra chromosome 14 as a possible cause of the extra bands' hybridizing to the μ heavy-chain constant-region probe. In the remaining ten patients, the presence of three or four bands hybridizing with the μ probe suggests the presence of two populations of leukemic cells that may have arisen either by separate leukemic transformation events or by clonal evolution of one clone into two related lines. Although preliminary (2-year follow-up), our data suggest that childhood ALL of B lineage with more than two μ heavy-chain genes, but without extra copies of chromosome 14, may be more resistant to therapy.

EVIDENCE INDICATES that most, if not all, non-T acute lymphoblastic leukemias (ALL) are of B cell lineage. Although blasts from only 20% of children with ALL of non-T origin express cytoplasmic immunoglobulin,[1,2] blasts from all of these patients contain rearrangements in the μ heavy-chain immunoglobulin genes.[3] Approximately 40% of these ALLs also contained rearranged light-chain genes. Rearranged μ heavy-chain genes are also found in a small percentage of T-ALLs[4,5] and myeloid leukemias,[6] but in these cases, light-chain genes are not rearranged. Thus, the definitive diagnosis of the B cell lineage often depends on a combination of gene rearrangement data and monoclonal antibody markers such as common acute lymphoblastic leukemia antigen (CALLA),[1] B4,[7] and p24.[8] This allows definition not only of lineage but also of the relative level of differentiation.[3,9]

Based on analysis of karyotype,[10] G6PD isoenzymes,[11] and the idiotype of B cell lymphoma immunoglobulins,[12] leukemia and B cell lymphomas appear to be clonal diseases. Immunoglobulin gene analysis provides further support for the clonal origin of leukemias and B cell lymphomas.[13] Since oligoclonal or polyclonal tumors would exhibit either multiple bands or no specific bands, immunoglobulin gene rearrangement can be used to examine not only the cell lineage but also the clonality of a leukemia.

We examined the arrangement of immunoglobulin heavy-chain genes in blasts obtained from children with acute leukemia of B lineage and in all cases found at least one μ heavy-chain gene rearrangement, confirming the results of Korsmeyer et al.[3] Unexpectedly, we also found a number of cases with more than two bands that hybridized to the μ constant (Cμ) probe. The biologic implications of this finding for the clonal origins of ALL as well as preliminary data on the response of these leukemias to therapy are discussed.

MATERIALS AND METHODS

Diagnosis and Treatment. The diagnosis of ALL was based on standard French-American-British (FAB) morphologic and cytochemical criteria.[14] Cytochemical studies including periodic-acid Schiff (PAS), myeloperoxidase (MPO), Sudan black B (SBB), chloroacetate esterase (CAE), and alpha naphthyl butyrate (ANB) staining were performed to exclude nonlymphoid leukemias.[15] All patients were the subjects of modern, intensive multiagent chemotherapeutic protocols that included CNS prophylaxis.[16-18] All studies were approved by the institution's Clinical Trials Committee, and informed consent was obtained from the patients and their parents.

Immunologic phenotype. Immunologic studies were done on bone marrow mononuclear cells after Ficoll-Hypaque (1.077 g/mL) density centrifugation; samples routinely had greater than 80% blasts. Only leukemic blasts with an immunophenotype consistent with early B cell origin were further analyzed, whereas those suggesting T cell origin were excluded. T cell origin was defined as reactivity with T-11, T101, or OKT3, or the formation of spontaneous rosettes with sheep erythrocytes. To identify cell surface antigens using monoclonal antibodies, leukemic cells were isolated and analyzed with a standard indirect immunofluorescence assay as described previously.[19] Samples with >40% of the cells demonstrating ring fluorescence were considered positive. For these assays, cells were first incubated in heat-inactivated pooled human AB serum to eliminate Fc binding. Isotypic myeloma immunoglobulin (Litton-Bionetics, Charleston, SC) was used at a concentration equal to the least-diluted monoclone as a negative control. Immunophenotyping studies included surface (sIg) and cytoplasmic immunoglobulin

(cIg), and lymphoid-associated antigens including p24, CALLA, and B4. The presence of terminal deoxynucleotidyl transferase (TdT) was determined by indirect immunofluorescence as previously described[20] and considered positive if greater than 40% of the cells were reactive. The HLA-DR (Ia-like) antigen was detected using the Ab279 antibody (Coulter Electronics, Hialeah, Fla).

Karyotype analysis. Chromosomes were prepared according to a direct bone marrow technique designed for ALL.[21] In each case, ten to 30 metaphases were studied for modal number and the presence of chromosome abnormalities. The karyotypes were determined by both direct microscopic analysis and photography.

Immunoglobulin gene rearrangement. Leukemic blasts were isolated from the bone marrow or peripheral blood by Ficoll-Hypaque gradients (1.077 g/mL); peripheral lymphocytes from volunteers were purified by the same procedure. DNA from lymphocytes was prepared as described by Wigler et al.[22] Twenty micrograms of DNA were digested with the appropriate enzyme, fractionated by electrophoresis on 0.8% agarose gels, and transferred to nitrocellulose paper.[23] Blots were probed with nick-translated DNA[24]; a 1.2-kb *Eco*RI fragment representing portions of the Cμ1 and Cμ3 domains and all of the Cμ2 domain of the μ heavy-chain gene,[25] a 2.5-kb germ line *Eco*RI fragment of the κ light-chain gene,[26] and a 3.4-kb *Hind*III/*Eco*RI piece of the heavy-chain joining region (J_H)[27] were used as probes. Inserts were purified from plasmids by agarose gel electrophoresis before nick-translation. After hybridization, the filters were washed at 56 °C in 0.1 × SSC (0.015 mol/L) sodium citrate, 0.15 mol/L sodium chloride, pH 7.0), 0.1% sodium dodecyl sulfate,[5] and 0.1% sodium dodecyl sulfate[5] and exposed to Kodak XAR film in the presence of intensifying screens.

RESULTS

μ heavy-chain immunoglobulin gene analysis in non-T ALL. The DNA from marrow or peripheral lymphoblasts of 93 children with non-T ALL was examined for the presence of rearranged immunoglobulin heavy-chain genes. All the patient samples were diagnostic of ALL, with typical lymphoblastic morphology and negative myeloid-associated cytochemistries (MPO, SBB, CAE, and ANB). Eighty-three of the patients expressed CALLA. Of the ten patients with blasts that did not express CALLA, six of the six tested expressed p24, all three tested expressed B4, and one patient's blasts contained cIg. At least one rearranged μ allele was found in all cases (Table 1). Twenty-three of the patients had one μ gene in the germ line configuration and one rearranged, whereas 37 showed rearrangement of both alleles. Fifteen patients demonstrated only one rearranged allele, indicating that the second allele had been deleted. Unexpectedly, 18 patients (19.4%) had more than two bands hybridizing to the Cμ probe.

Clinical and laboratory characteristics of patients with greater than two μ gene bands. The clinical and biologic characteristics of 18 ALL patients with greater than two bands hybridizing with the heavy-chain gene probe are summarized in Table 2. The median age was 3.4 years (range, 1.3 to 13.7 years), and there were 12 girls and 6 boys in this group. The median initial circulating leukocyte count was 36.2×10^9/L (range, 1.8 to 345.0×10^9/L), higher than might be expected for a group of children with early B lineage leukemia, but not significantly different statistically by the two-tailed *t* test from the other 75 patients studied ($P = .38$). Sixteen of the 18 patients were classified as FAB-L1 and two as L2. Of the 17 patients tested, 14 expressed TdT.

Table 1. Arrangement of Immunoglobulin μ Heavy-Chain Genes in ALL

Type of ALL	1°	$1^{+}1^{\circ}$	$1^{+}1^{d}$	2^{+}	>2	Total
CALLA$^-$	0	3 (27%)	2 (18%)	3 (27%)	3 (27%)	11
CALLA$^+$	0	20 (24%)	13 (16%)	34 (41%)	15 (18%)	82

Abbreviations: $^{\circ}$, germline configuration; ^{d}, deleted allele; $^{+}$, rearranged allele.

None of the patients blasts expressed T cell–associated surface antigens. Blasts from all 17 patients tested were HLA-DR (Ia) positive, and 14 expressed CALLA. Blasts from the three CALLA$^-$ patients expressed p24. Of the 17 patients from this group examined for cIg, six (35%) were positive.

Cytogenetic analysis. The karyotypes of all 18 patients are shown in Table 3. The modal number of the karyotypes at the time of diagnosis was 45 ($n = 1$), 46 ($n = 6$), 47 to 49 ($n = 2$), and >50 ($n = 9$). Eight of the nine patients with more than 50 chromosomes had an extra copy of chromosome 14 (patients 3, 8, 13 to 18). None of the remaining patients with less than 50 chromosomes had an extra chromosome 14. Numerous structural abnormalities, including six reciprocal translocations, were present in these cases, but none involved chromosome 14. Three patients contained marker chromosomes that have neither the size nor the banding pattern of a normal chromosome 14. In none of the karyotypes is there clear evidence of multiple independent clones. However, in one of the patients (no. 2), there were two related lines.

Heavy-chain gene rearrangements in patients with more than two μ gene bands. A representative Southern blot with DNA from eight of the patients is shown in Fig 1. Four of the patients (1, 2, 6, and 7) had four bands that hybridized with the μ probe, and the others demonstrated three μ-hybridizing bands (patients 3, 4, 5, and 8). The presence of a germ line μ-gene band in patients 3 and 5 cannot be due to the presence of normal cells because the percentage of contaminating normal cells in the preparation was significantly below the percentage of germ line DNA as determined by scanning densitometry (data not shown). The detection of cIg indicates that productive rearrangements had occurred in patients 5, 7, and 8.

To eliminate the possibility that the extra bands represent the presence of a polymorphic *Bam*HI site in these patients, nine of the patients' DNAs were examined further with *Hind*III digestion and J_H probing, and four were further examined by *Eco*RI digestion and J_H probing. The results, summarized in Table 4, were always consistent with the *Bam*HI digestion and Cμ probing results. These experiments eliminate other explanations for the extra Cμ-hybridizing bands, such as incomplete digestion of the DNA or somatic mutation.

Light-chain gene rearrangement. Sufficient DNA was available from 11 of the 18 patients to examine the arrangement of the κ light-chain genes. A κ constant-region probe demonstrated a germ line configuration for nine of the 11 DNAs (Table 4), with the remaining two DNAs (18.2%)

*The number of heavy-chain genes indicated is based on the *Bam*HI probing and was confirmed by use of the other enzyme and probe combinations listed.

onstrated only one neoplastic clone with a t(2;16) translocation However, at relapse the t(2;16) abnormality could not be found, and a clone with the t(4;11) translocation was present (Table 3). Extensive analysis of metaphases from diagnosis did not demonstrate the presence of the t(4;11).

At diagnosis, four $C\mu$-hybridizing bands were present, all rearranged, but at relapse only two rearranged and one germ line band were present (Fig 1). The germ line band present at relapse probably resulted from the normal cells (30%) that were in the preparation used for DNA extraction. Since no DNA remained from diagnosis, we were unable to directly compare the sizes of the μ genes in both samples. However, the similarity in size of two of the bands from diagnosis (the bottom two bands) with the two non–germ line bands present at relapse suggests conservation (persistence) of the immunoglobulin μ-gene rearrangements from one clone.

DISCUSSION

Our findings confirm that in B precursor cell ALL at least one copy of the immunoglobulin μ heavy-chain gene is always rearranged.[3,9,28,29] The differentiation stage of our patient population appears earlier than other studies since only 21% had rearranged κ light-chain genes, compared with about 40%.[3] Because of the large percentage of early B precursor ALLs without light-chain gene rearrangement and the finding that μ heavy-chain gene rearrangements occur in about 20% of non–B cell leukemias,[4-6,30,31] immunoglobulin gene rearrangement data by itself cannot always be used as a definitive marker of B cell lineage. This data must be correlated with immunologic data to establish the B precursor cell origin of ALL.

An unexpected finding of this study was that DNA from 18 of 93 (19.4%) patients had more than two bands that hybridized to the $C\mu$ probe. This result was surprising because in the extensive studies of Korsmeyer et al[3,13,28] no cases with more than two μ-gene–hybridizing bands were reported. To rule out trivial explanations such as incomplete enzyme digestion or allelic variation in the *Bam*HI sites, we used several different combinations of restriction enzymes (*Eco*RI and *Hin*dIII) and μ-gene probes ($C\mu$ or J_H). For the nine patients analyzed by *Hin*dIII digestion and J_H probing and the four analyzed by *Eco*RI digestion and J_H probing, the results were entirely consistent with the *Bam*HI digestion and $C\mu$ probing, confirming the presence of more than two hybridizing bands. Data similar to ours has been noted by Foa et al[32] who found that five of 19 (26%) patients examined had three bands hybridizing to a J_H probe. These authors used both *Eco*RI and *Sac*I digests to confirm their findings Thus, in two independent studies, between 19% to 26% of the patients examined had more than two μ-gene–hybridizing genes in their leukemic clones at diagnosis. We do not know the reason(s) why Korsmeyer et al[3] did not detect such patients. Possibly there could be fundamental clinical and/or biologic differences in the patient populations studied by us, Foa et al (patient's ages were not given), and that studied by Korsmeyer et al.

We considered two alternative explanations for the presence of the extra bands: (1) It is possible that extra copies of chromosome 14 were present and the rearrangements of the μ heavy-chain gene on the duplicated chromosome differs from that of the parent chromosome. (2) Two populations of cells were present, either related by clonal evolution, or unrelated and the product of two separate transformation events (biclonal).

Detailed examination of the karyotypes of the 18 patients demonstrated that eight had extra copies of chromosome 14 (Table 3); this is a known characteristic of the greater-than-50 ploidy group.[33] However, in only four patients (nos. 3, 8, 13, and 15) did the number of copies of chromosome 14 agree with the number of bands seen on Southern blots. Of the remaining four patients, one (no. 14) had four copies of chromosome 14 but only three μ-gene–hybridizing bands. Analysis of the gel from this patient revealed that hybridization to one of the three bands was greater than that to the other two, suggesting that the same gene rearrangement may be present on two copies of chromosome 14 (data not shown). Three patients (nos. 16 to 18) had four copies of the μ gene but only three copies of chromosome 14. In two of these patients (nos. 17 and 18), germ line μ-gene bands were present, and although differential blast counts were over 90% for these two patients, it is possible that sufficient normal cells were present to allow us to detect the germ line μ gene. Thus, except for the remaining patient with three copies of chromosome 14 and four Cμ-hybridizing bands, the data indicate that the extra copy or copies of chromosome 14 is responsible for the presence of more than two bands that hybridize with the μ-chain gene probes in this group of patients. These results also suggest that the rearrangement of the μ heavy-chain gene can occur after the occurrence of chromosomal duplication.

Although extra copies of chromosome 14 may be an explanation for the presence of extra μ-gene–hybridizing bands in some patients, in the majority of patients only the normal number of copies of chromosome 14 were present. In these cases, the data lead us to conclude that more than one population of cells is present. The second population could be the result of either separate leukemic transformation events, ie, biclonal leukemia, or could represent sublines that have evolved from the original clone. There is precedent for both of these possibilities.

Biclonal B cell lymphomas have been identified by Sklar et al.[34] Each biclonal tumor contained cells bearing individually distinctive idiotypes. The presence of each idiotype on different cells was confirmed by cell sorting and the contribution of each cell population to the μ heavy-chain gene pattern on Southern blots determined. Such cell-sorting experiments are not possible with the types of leukemias studied here since all are very early B cell precursors, none had sIg, and most do not even express cytoplasmic immunoglobulin (Table 2). Independently arising clones would be expected, however, to have different cytogenetic abnormalities, and two distinct stem lines were not found in the karyotypes of any of the patients (Table 3). We do not therefore believe that biclonality is the explanation for our findings of more than two Cμ-hybridizing bands in the ten patients without extra copies of chromsome 14.

The more likely explanation is clonal evolution involving continued rearrangement of the Ig genes after leukemic transformation. Growth of clonal lines of Abelson murine leukemia virus (A-MuLV)-transformed null (pre-B) mouse lymphoid cells is accompanied by continued rearrangement of the heavy-chain genes.[35] Alt et al[35] postulate that the initial Ig gene rearrangements involved D_H-J_H joinings, which could be rearranged further by the substitution of another D_H segment or by the addition of a V_H segment to the existing D_H-J_H complex These results have recently been confirmed and extended by Whitlock et al[36] who showed that A-MuLV transformants of a cloned mouse pre–B cell population exhibited multiple heavy- and light-chain Ig gene rearrangements. Thus, in the murine lymphoid leukemic cell counterparts to human pre-B lymphoid leukemias, transformation does not preclude further rearrangements in the Ig gene loci. If this mechanism is responsible for the generation of the two cell populations in the human leukemias we have examined, proof could come from cloning the genes and examining the V_H-D_H-J_H junctions. Such studies are in progress.

Although all patients received intensive multiple-agent chemotherapy,[16–18] eight of the 18 with more than two Cμ-gene bands have relapsed. Interestingly, there appears to be a direct correlation between the treatment outcome and karyotype in this group of patients. Seven of the eight patients with an extra chromosome 14 remain in continuous complete remission with a median follow-up of 1.5+ years (range, 0.9 to 1.8+ years), consistent with our previous observations of the comparatively good prognosis of hyperdiploid ALL.[37] In contrast, of the ten patients without an extra chromosome 14, only three remain in complete continuous remission (1.8+, 2.0+, and 3.0+ years) with a median time to relapse of 0.95 years (range, 0.2 to 2.2 years) Although these results must be considered preliminary because of the number of patients and length of follow-up, they are consistent with clonal evolution and further somatic mutation as a mechanism underlying leukemic progression and acquisition and emergence of drug resistance.[38–40]

In summary, we have found that around 20% of childhood ALLs at diagnosis have more than two Cμ-hybridizing bands, which can be the result of either extra copies of chromosome 14 or of clonal evolution. The presence of extra Cμ-hybridizing bands without an extra chromosome 14 seems to be correlated with a risk of early relapse.

ACKNOWLEDGMENT

We would like to thank Drs Philip Leder, Terence Rabbitts, and Carlo Croce for cloned probes and Ann Tipler and Janet Winkler for providing excellent technical assistance The authors would also like to thank Dr Alvin M Mauer for his support and encouragement and all the physicians and nurse practitioners of the Leukemia Division for their dedicated assistance in obtaining patient samples.

Lymphocyte Malignancy and Chromosome 14: Structural Aberrations Involving Band q11

By Nanette Clare, David Boldt, Gerald Messerschmidt, Paul Zeltzer, Kathryn Hansen, and Louis Manhoff

Five patients with lymphocytic malignancies were found to have structural aberrations of chromosome 14, all involving band q11. The malignant cells of all five cases were analyzed by immunofluorescence to establish immunologic phenotypes. Three patients had T lymphoblastic lymphoma/leukemia with mediastinal masses (cases 1, 2, and 3); one patient had peripheral T cell lymphoma (case 4); and one patient had acute lymphocytic leukemia, common acute lymphoblastic leukemia antigen positive (case 5). Although aberrations of chromosome 14 frequently are associated with lymphocytic malignancies, these abnormalities most often result in extra material on the long arm, 14q+. However, none of the five patients reported here had a 14q+. Cases 1 and 2 had t(9;14)(q34;q11) and t(11;14)(p11or13;q11), respectively. Case 3 showed del(14)(q11), and cases 4 and 5 showed inv(14)(q11q32). Structural aberrations resulting in 14q− and inv(14) appear to occur infrequently. The five cases in this report, in conjunction with those found in the literature, indicate a strong association between breaks at 14q11 and T lymphocytic malignancies.

© 1986 by Grune & Stratton, Inc.

CYTOGENETIC analyses of lymphocytic malignancies are being reported with increasing frequency. Structural abnormalities of chromosome 14 have been commonly found, particularly the t(8;14)(q24;q32) seen in Burkitt's lymphoma and other types of B lymphocytic malignancies.[1-3] Most structural aberrations of chromosome 14 associated with lymphocytic disorders result from translocations of significant portions of other chromosomes to chromosome 14, showing 14q+ with the break point at band 14q32, the location of the heavy-chain gene for immunoglobulin. Only rarely is there a major loss or translocation of no. 14 resulting in a 14q−.

Chromosome analysis of the lymphomas has not progressed as rapidly as that in leukemia, principally because of the technical problems of obtaining sufficient numbers of cells in mitosis from solid tissue There have been few reports of chromosome findings in T cell disorders, most occurring in T-chronic lymphocytic leukemia (T-CLL) or cutaneous T cell lymphoma (CTCL). Some authors report minimal or no involvement of no. 14,[4-6] whereas more recent studies have shown structural aberrations involving band q11. These have consisted either of an inversion, inv(14)(q11q32), or translocation resulting in 14q−[7-10] These are new and unusual chromosome aberrations of lymphocytic malignancies that occur principally in T cell disorders.

Reported here are five cases of lymphocytic malignancies with abnormalities involving 14q11. Four of these cases were classified as T cell malignancies and one as acute lymphocytic leukemia, pre–B cell type.

CASE HISTORIES

Case histories and pertinent data are summarized in Table 1

MATERIALS AND METHODS

Bone marrow aspirations and biopsies were performed on each patient after informed consent

Cell surface markers Cell suspensions prepared from bone marrow or peripheral blood by density sedimentation on Ficoll-Hypaque[13] were examined for reactivity with panels of commercially available, well-characterized mouse monoclonal antibodies to human lymphocyte antigens. Monoclonal antibodies and their specificities were as follows: T11, total T cells and thymocytes; OKT3 and anti–leu-1, mature T cells and mature thymocytes; OKT4, T-helper cells and mature thymocytes; OKT6, cortical thymocytes; OKT8, T-suppressor cells and mature thymocytes, OKT9 and OKT10, early thymocytes and other hematopoietic cell precursors, J5, anti–common acute lymphoblastic leukemia antigen (CALLA) on leukemia cells and normal lymphoid precursor cells; B1 and B4, total B cells; I2, anti-Ia antigen Monoclonal reagent anti–leu-1 was obtained from Becton-Dickinson Monoclonal Antibody Center, Sunnyvale, Calif; T11, I2, B1, B4, and J5 from Coulter Immunology, Hialeah, Fla; and all others from Ortho Diagnostics, Westwood, Mass

Expression of T and B lymphocyte surface markers by malignant cells was assessed by indirect immunofluorescence and flow cytometry[14] Briefly, 1 to 2 × 10^6 cells were incubated for 30 minutes at 4 °C with an appropriate dilution of monoclonal antibody. Cells were washed twice, then incubated for an additional 30 minutes at 4 °C with a 1:50 dilution of fluorescein-conjugated goat antimouse IgG. After two additional washes, cells were suspended in 1% buffered paraformaldehyde, then analyzed by flow cytometry on a Coulter TPS 1 fluorescence-activated cell sorter with a 2W laser. (Patient 2 was analyzed on an Ortho Cytofluorograph) In parallel incubation to control for nonspecific binding, cells were incubated with mouse ascites fluid containing nonrelevant immunoglobulin in place of specific monoclonal antibody during the first step, but otherwise were treated identically

Cytochemistry. Cytochemistry techniques used to analyze malignant cells were those in routine use in our clinical laboratories.[15] They include myeloperoxidase, Sudan black B, ASD-chloroacetate esterase, alpha napthyl butyrate esterase with and without sodium fluoride, periodic-acid Schiff (PAS), and acid phosphatase. Terminal deoxynucleotidyl transferase (TdT) was assayed on fixed smears by an immunofluorescent method.[16]

Cytogenetics Initial specimens were received from each patient at the time of diagnosis, prior to therapy. Peripheral blood, 1 to 10 mL, or 0.5 mL bone marrow (patient 3) was collected in EDTA anticoagulant[17] and kept at 4 °C until received in the cytogenetic laboratory the same day There was not sufficient bone marrow aspirate from patients 1, 2, 4, or 5 for cytogenetic analysis The specimens were processed by a modification of the standard direct harvest procedure,[18] unstimulated 24-hour culture, and/or by incu-

*Peripheral WBC count per μL

bation in media with phytohemagglutinin for 48 to 96 hours [19] Slides were stained with trypsin-Giemsa for G-bands.[20] Additional bone marrow and peripheral blood specimens were obtained from patients 2 and 5 during complete remission. The bone marrow (1 mL) was received in EDTA and processed by direct harvest. The peripheral blood (10 mL) was received in sodium heparin and processed by a 72-hour incubation with phytohemagglutinin Slides from both samples were G-banded as previously.

RESULTS

Cell surface markers. Results of surface marker studies and cytochemistry are given in Table 2.

Cytogenetics. The cytogenetic results are summarized in Fig 1 and Table 3.

The majority of cells analyzed in cases 1 and 4 were obtained from the 72-hour phytohemagglutinin-stimulated cultures. In case 1, five of eight cells present in the direct harvest were found to have the abnormal karyotype. The chromosome 9 involved in the translocation with the 14 also showed a terminal deletion of the short arm at p21 as the only other aberration present. Case 4 contained t(9;?) (q34;?) and t(13;?) (p12?;?) in addition to the inv(14)(q11q32). The origin of the 9q+ material was not determined; the t(13;?) was suggestive of a 13;21 translocation.

The cells analyzed in cases 2 and 3 were obtained by direct harvest. The banding was not of sufficient quality in case 2 to determine the exact break point in the 11, appearing to be at either p11 or p13. The 14q− is longer in this case than in cases 1 and 3 because of the translocated 11p material. The abnormality in case 3 may actually represent a 7;14 translocation; however, this could not be identified with certainty. The majority of cells analyzed in case 5 were obtained by 24-hour unstimulated culture.

DISCUSSION

Five cases of lymphocytic malignancies are reported with chromosome aberrations involving band 14q11. In two cases the abnormality consisted of a translocation, in one case a deletion, and in two cases a paracentric inversion. In none of the cases did the abnormality result in 14q+.

Lymphocyte surface marker data were available for all five patients. Abnormal lymphocytes marked as T cells in four patients (cases 1, 2, 3, and 4) and as pre–B cells in one patient (case 5). Cells from patients 3 and 4 had similar phenotypes. These cells expressed the E rosette receptor as detected by reactivity by monoclonal reagents T11 and anti–leu-5. In case 4 the cells also expressed the T3 antigen, and in cases 3 and 4 both helper (T4/leu-3)- and suppressor (T8/leu-2a)-specific antigens were present. The phenotypes were T11+T3+T4+T8+CALLA-Ia-Bl-. This phenotype is most consistent with a level of maturation at the stage of the common thymocyte.[21] The T10 positivity observed in case 4 further supports a thymocyte origin.

Less extensive data were available for case 2, but the TdT positivity together with high levels of expression of T11, leu-1, and T3 is most consistent with a thymocyte level of maturation Case 1 was characterized by relatively low levels of reactivity with all monoclonal reagents. Evidence supporting a T cell derivation includes expression of the T11, T6, and T10 antigens as well as polar acid phosphatase positivity. Expression of T6 and T10 but not T3, T4, or T8 places the

level of maturation at an early thymocyte stage. In case 1, 12% of the lymphoblasts also expressed CALLA. CALLA-positive T cell malignancies have been previously recognized[22–24] The phenotype of case 5 was CALLA-positive, TdT-positive, IA-positive, and B4-positive. This is characteristic for pre-B ALL.[21]

T cell disorders have been, until recently, reported only rarely in this country. This is most likely due to inexperience in detecting T cell malignancies histologically and to a lack of obtaining marker studies in diffuse lymphomas. It is likely that T cell malignancies are more prevalent than originally thought. The majority of cytogenetic analyses of T cell malignancies reported are T-CLL and CTCL.[7–9,25–32] Classification of T cell malignancies is in the formative stages, and as marker studies become standard procedures, an improved classification may result. With the morphology, cytochemistry, and surface marker data, the cases reported here were classified as T cell lymphoblastic lymphoma/leukemia (cases 1 to 3), peripheral T cell lymphoma (case 4), and ALL, pre-B type (case 5).

The majority of lymphocytic malignancies with chromosome aberrations reported in the literature to date involve structural and/or numerical aberrations of chromosome 14. Most of these structural aberrations involve the terminal band on the long arm, 14q32, and consist of a translocation, 14q+, with chromosome 14 being the recipient of a major portion of another chromosome. This type of abnormality was described originally in Burkitt's lymphoma,[33] but it has been seen also in lymphocytic malignancies. Although t(8;14) is most common, t(2;8) or t(8;22) have also been reported.[2,3] These observations had led to speculation that the 8q− may be more significant in the development of malignancy than the 14q+.[1] However, it has recently been found that the *c-myc* oncogene, located at 8q24, is deregulated when involved in the translocations.[2] In the t(8;14) the break point in no. 8 is directly proximal to the *c-myc* locus so that it is translocated to the 14q32 at various sites of the heavy-chain locus, frequently involving the μ-chain switch region. The t(2;8) and t(8;22), on the other hand, involve a break point on no. 8 just distal to the *c-myc* locus so that the λ-chain locus from no. 22 and the κ-chain locus from no. 2 are attached to that site.[2] These rearrangements most often involve B cell malignancies.

Cytogenetic analysis is proving to be important in the accurate diagnosis and possibly in the prognosis of lymphocytic lymphomas,[34,35] and there are two reports that suggest it may have predictive value. McCaw et al[10] studied T lymphocytes in ataxia telangiectasia and found five cases showing

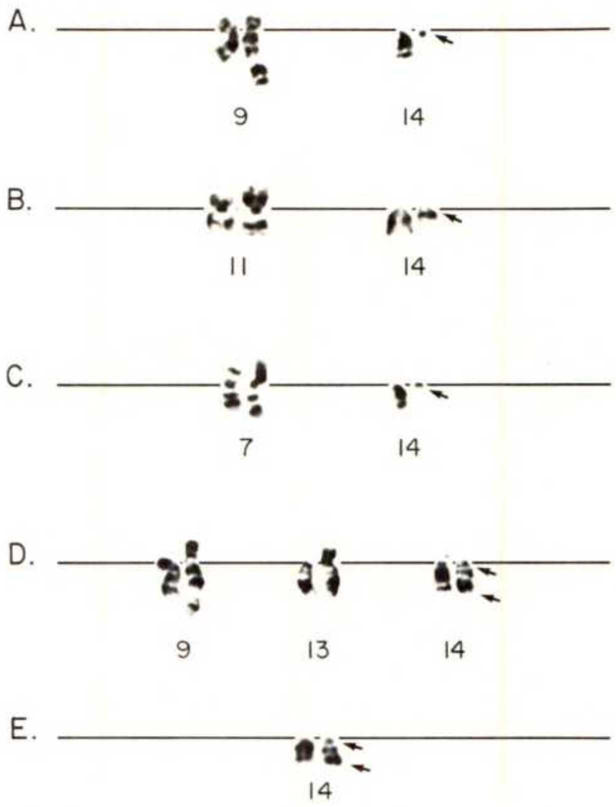

Fig 1. Partial karyotypes of patients 1 to 5, A to E, respectively, showing chromosome aberrations (G-band with trypsin-Giemsa). (A) del(9)(p21),t(9;14)(q34;q11). (B) t(11;14)(p11or13;q11). (C) 7p+,del(14)(q11). (D) t(9;?)(q34;?),t(13;?)(p12?;?),inv(14)(q11q32) (E) inv(14)(q11q32).

14q– or Dq– that were very similar in appearance to a break at 14q11 (these were not included in Fig 2). Chronic lymphocytic leukemia that involved the clone with t(14q–;14q+) developed in one of these patients. Fukuhara et al[36] demonstrated clonal aberrations in stimulated peripheral lymphocytes of two healthy adult carriers of adult T cell leukemia–associated antigen; these may prove to be markers of a premalignant clone.

Chromosome 6 has also been implicated as being frequently involved in numerical or structural aberrations of T cell disorders. Miyamoto et al[39] reported 17 of 30 patients with either trisomy 6 or 6q–, and Whang-Peng et al[40] found 6q deletions in six of 11 patients with T cell leukemia/lymphoma. These six patients shared several clinical findings and had a significantly shorter survival than patients without 6q–. This may indicate prognostic significance of chromosome 6 abnormalities in T cell disorders.

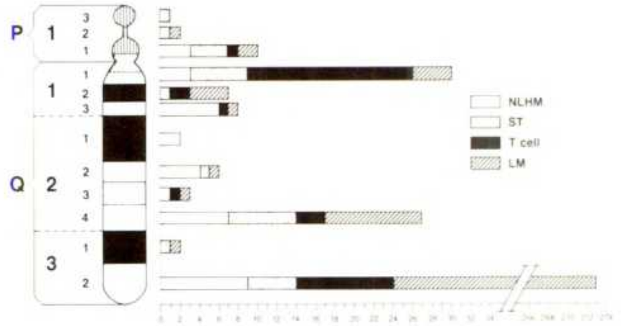

Fig 2. Diagram of chromosome 14 showing the number of different malignant disorders involving aberrations of the various bands. From references 7–9, 25–32, 36–38 and present cases. Abbreviations: NLHM, nonlymphocytic hematopoietic malignancy; ST, solid tumor; T cell, T cell lymphocytic malignancies; LM, lymphocytic malignancies, non–T cell.

Figure 2 is a diagram of chromosome 14 showing the relative incidence of aberrations involving the various bands of the chromosome. There is difficulty in constructing this kind of chart since many reports do not include surface marker studies. For the purpose of simplicity, all B cell disorders and some of those that were not differentiated were included in the category of lymphocytic malignancy (LM). Only those cases proven to be T cell malignancies by marker studies and/or cytochemistry were placed in the category of T cell. The diagram emphasizes the overwhelming number of cases involving band q32. Of note, only 3.6% (10/273) of these cases can be shown conclusively to be T cell disorders.[30-32,37] The T cell disorders listed with aberrations involving 14q32 include only those with a single break point. If the cases with two break points involved are included (q11 and q32),[7-9,32] then 7% (20/284) of cases affecting 14q32 are T cell disorders. Case 5 of this report would be included as LM at q32. The band of chromosome 14 involved next most commonly with malignancies is q11. Of all malignancies associated with the q11, 56.6% (17/30) can be classified as T

Table 3. Cytogenetic Analysis, Trypsin-Giemsa Banding

Case No.	Specimen	No. Cells Counted/Analyzed	Karyotype
1	PB, pretreatment	54/44	46,XY,del(9)(p21),t(9;14)(q34;q11)—45% 46,XY—55%
2	PB, pretreatment	39/28	46,XX,t(11;14)(p11 or 13;q11)
	BM, remission	37/25	46,XX

	BM, remission	30/25	46,XY

Abbreviations: PB, peripheral blood; BM, bone marrow.

cell in origin. If the LM are considered separately, T cell disorders account for 81% (17/21). Therefore, whereas band 14q32 is strongly associated with B lymphocyte malignancies, band 14q11 appears to be associated with T cell malignancies.

A recently published report by Hecht et al[41] also shows this association, with three cases of T cell malignancies having breaks at 14q11. The authors also state that rearrangements of chromosome 14 that result in approximation of 14q32 to 14q11 have only occurred in T cell malignancies. Case 5 in this report, however, has inv(14) (q11q32) and is a pre-B ALL.

Analysis of the T cell disorders involving clonal aberrations of 14q11[7,8,9,32,38] shows eight of 17 to be inv(14) (q11q32), eight of 17 to involve a translocation with chromosomes 9 (three cases), 14 (two cases), 4, 11, and 17 (one case each), and one of 17 to involve a deletion that may actually be a t(7;14). There is no preferential involvement of any other chromosomes with these 14q11 abnormalities. The importance of band 14q32 in T cell disorders cannot be dismissed, since ten of 17 cases involve breaks of both 14q11 and q32 [t(14;14) and inv(14)]. Recent reports[7,8,9,35] have also stressed the association of T cell disorders and aberrations of 14q11; these cases have been predominantly T-CLL and CTCL. The present cases show that this aberration may occur in other types of T cell disorders as well. It is important and interesting to note that Croce et al[42] have most recently mapped the gene for the α chain of the T cell receptor to chromosome 14 in the region q11-q12. A break in this region likely results in a different environment for this gene, analogous to translocations in B cell malignancies involving the immunoglobulin heavy-chain and light-chain loci. Further studies may also implicate oncogenes in these aberrations, as speculated by Croce et al.[42]

Calcium Accumulated by Sickle Cell Anemia Red Cells Does Not Affect Their Potassium ($^{86}Rb^+$) Flux Components

By Olga E. Ortiz, Virgilio L. Lew, and Robert M. Bookchin

We investigate here the hypothesis that the high Ca content of sickle cell anemia (SS) red cells may produce a sustained activation of the Ca^{2+}-dependent K^+ permeability (Gardos effect) and that the particularly high Ca levels in the dense SS cell fraction rich in irreversibly sickled cells (ISCs) might account for the Na pump inhibition observed in these cells. We measured active and passive $^{86}Rb^+$ influx (as a marker for K^+) in density-fractionated SS cells before and after extraction of their excess Ca by exposure to the Ca ionophore (A23187) and ethylene glycol tetra-acetic acid and with or without adenosine triphosphate depletion or addition of quinine. None of these maneuvers revealed any evidence of a Ca^{2+}-dependent K leak in SS discocytes or dense cells. Na pump inhibition in the dense SS cells was associated with normal activation by external K^+ and a low V_{max} that persisted after Ca extraction from the cells. These results are consistent with our recent findings that the excess Ca in these cells is compartmentalized in intracellular inside-out vesicles and unavailable as free Ca^{2+} to the inner membrane surface. Although the steady-state free cytoplasmic Ca^{2+} in oxygenated SS cells must be below the levels needed to activate the K^+ channel, possible brief activation of the channels of some SS cells resulting from transient elevations of cell Ca^{2+} during deoxygenation-induced sickling cannot be excluded. The dense, ISC-rich SS cell fraction showed a Ca^{2+}-independent increase in the ouabain-resistant, nonsaturable component of $^{86}Rb^+$ influx that, if uncompensated by Na^+ gain, could contribute to the dehydration of these cells.
© 1986 by Grune & Stratton, Inc.

BECAUSE of the high-power–concentration dependence of hemoglobin (Hb) S polymerization,[1] the mechanism by which a substantial proportion of sickle cell anemia (SS) red cells become dehydrated has been the subject of intense scrutiny. A candidate often implicated in the dehydration has been the Ca^{2+}-sensitive K^+-selective channel[2,3] since, in principle, the documented high Ca content of SS cells could activate the channel, causing net KCl loss and cell shrinkage. Although measurements of $^{42}K^+$ fluxes in fresh, substrate-fed SS red cells in the presence and absence of quinine have ruled out any large increase in Ca^{2+}-dependent K^+ fluxes,[4] possible minor, sustained increases in K^+ flux, particularly in the dense SS cell fraction rich in irreversibly sickled cells (ISCs) in which the highest Ca levels are found,[5,6] have not yet been excluded. If present, such an uncompensated K^+ efflux could lead to slow cumulative shrinkage of the cells.

It has also been suggested that the high Ca content of ISCs might account for the Na pump inhibition observed in this SS cell fraction.[7] Such an abnormality could not itself account for cell dehydration but should be detectable if a substantial fraction of the total Ca content of ISCs were present as free ionized Ca in the cytoplasm.[8]

To assess the possible role of endogenous SS cell Ca in active and passive K^+ fluxes, we measured the influx of $^{86}Rb^+$ as a marker for K^+ in density-fractionated SS cells before and after extracting all their mobilizable Ca by exposure to ionophore and ethylene glycol tetra-acetic acid (EGTA) under a variety of conditions designed to reveal K^+-channel activity. The results confirmed Na pump inhibition in the ISC fraction and showed evidence of an increase in nonsaturable ouabain-resistant $^{86}Rb^+$ influx in the same cells. But there was no evidence of endogenous Ca effects on either pump or leak in any SS cell fraction.

MATERIALS AND METHODS

Heparinized venous blood was obtained with informed consent from normal donors and from patients with SS whose genotype has been established by electrophoretic and family studies at our Heredity Clinic The blood was kept refrigerated at 4 °C, and all experiments were performed within 24 hours of venesection The plasma and buffy coat were removed by aspiration after centrifugation, and the RBCs were routinely washed four times (unless stated otherwise) in the buffer appropriate to each experiment.

Density gradient separation of RBCs Density fractionation of the RBCs followed the method of Corash et al[9] with minor modifications. The RBCs were washed and suspended at a 20% hematocrit (HCT) value in buffered saline with potassium and glucose (BSKG) containing (in mmol/L) NaCl, 134, KCl, 5; glucose, 2; and Na-phosphate buffer, 10, pH 7.4 (37 °C), adjusted to 291 mosm with a Micro Osmometer, Model 5004 (Precision Systems, Sudbury, Mass)

Stractan (arabinogalactan, St Regis Paper Co, Libby, Mont) was dissolved in water and deionized by successive-batch equilibrations for several hours each at 4 °C with AG501-X8(D)20 50–mesh mixed-bed resin (Bio-Rad Laboratories, Richmond, Calif) until the pH had fallen to about 3.0 and the osmolarity to 100 mosm or less After the last filtration to remove the resin, the Stractan solution was centrifuged at 20,000 g for 45 minutes at 4 °C This stock solution, about 40% (wt/wt) Stractan, density 1.163 to 1.170, was diluted with BSKG to obtain four additional densities, 1.087, 1.095, 1 105, and 1 118, as measured on a refractometer (Model 33-45-58, Bausch and Lomb, Austin, Tex), centrifuged again for 30 minutes, passed through a 0.45-μm filter (type S, Nalgene, Rochester, NY), and stored frozen A discontinuous gradient was made by layering 2.5 mL of each of these four density solutions onto a cushion of 0.5 mL of the stock solution in 12-mL plastic centrifuge tubes; 1 mL of the 20% RBC suspension was layered onto each gradient tube, and they were centrifuged for 45 minutes at 17,000 rpm in an SS24 angle rotor of a Sorvall RC2B centrifuge (Ivan Sorvall, Newtown, Conn.) at 4 °C. The RBC bands were harvested with a Pasteur pipette and, after washing in the appropriate buffer, were sampled into buffered formalin for morphologic evaluation using a Zeiss microscope

equipped with Nomarsky optics. Cells were designated ISCs if their length exceeded their width by a factor of two or more. Small crumpled RBCs seen in the dense fractions, which did not meet the criteria for ISCs, were designated deformed Cells with a density between 1 095 and 1.105 were 94% to 95% discocytes, with less than 1% reticulocytes seen on films stained with new methylene blue, and were used as the discocyte fraction; cells with a density between 1 118 and 1.163 were 68% to 73% ISCs, 18% to 19% deformed, and 11% to 14% discocytes and were used as the ISC-rich fraction.

Removal of endogenous RBC calcium. Cells were washed in buffer A containing (in mmol/L) NaCl, 75; KCl, 75; EGTA, 0 1, and Na-HEPES, 20, pH 7 6 (20 °C), 291 mosm. They were then suspended at a 30% HCT value in the same medium containing, in addition, 1 mmol/L EGTA, 0.2 mmol/L $MgCl_2$, and 10 μmol/L of the calcium inophore A23187 (Sigma Chemical Co, St Louis) and incubated at 37 °C for 15 minutes. The concentrations of Na^+, K^+, and Mg^{2+} in the medium were chosen to maintain cell concentrations of cations (other than Ca) in the presence of A23187 and EGTA in the Ca^{2+}-free medium.[10] Following incubation, the suspension was chilled on ice and diluted with 4 vol of buffer A containing 1 mmol/L EGTA, 10 mmol/L inosine, and 1% bovine serum albumin and washed twice with the same solution to remove all A23187 from the cell membranes and twice with the buffer appropriate to the experiments.

Depletion of RBC adenosine triphosphate The RBCs were washed in buffer A, resuspended at a 20% HCT value in the same medium with the addition of 10 mmol/L inosine and 6 mmol/L iodoacetamide,[11] incubated at 37 °C for 90 minutes, and then washed thrice in the appropriate buffer. The adenosine triphosphate (ATP) content of the RBCs, measured by the firefly technique,[12] was 0.8 to 1.0 mmol/340 g Hb in the fed cells, and after depletion, was less than 20 μmol/340 g Hb.

Measurements of $^{86}Rb^+$ influx in RBCs. For measurements of $^{86}Rb^+$ influx as a function of external K^+ concentration, illustrated in Fig 1, the procedure of Glynn[13] was used with modifications. Discocyte and ISC-rich SS cell fractions were washed in 4 vol of buffer B containing (in mmol/L) NaCl, 150; $MgCl_2$, 1; $CaCl_2$, 1; glucose, 2; and Tris-phosphate, 2.5, pH 7.4 (37 °C) at 4 °C. The packed cells were resuspended at a 5% HCT value in cold incubation medium, and solid glucose and ouabain were added to give final concentrations of 10 mmol/L and 10^{-4} mmol/L, respectively When K^+ was present in the medium, the Na^+ concentration was (150 − K^+) mmol/L. $^{86}Rb^+$ was added as $^{86}RbCl$, 10 mCi/mg, (New England Nuclear, Boston) to provide a 10 μCi/mL suspension, and after taking zero-time samples at 0 °C, the suspensions were transfered to a 37 °C water bath with magnetic stirrers and sampled again at 20, 40, and 60 minutes. Samples of 100 μL of RBC suspension were delivered to 1.5 mL Eppendorf tubes in an ice bath containing 0 4 mL dibutyl phthalate (d^{20} = 1 047) (Matheson, Coleman and Bell, Norwood, Ohio) and 0.9 mL of K^+-free buffer B; the tubes were inverted and immediately spun for 10 seconds at 13,000 rpm in an Eppendorf microcentrifuge.[10] After aspiration of the supernatant, the tube walls were wiped with cotton swabs, the RBC pellets lysed by the addition of 0.1 mL of water containing 0.1% Triton X-100 (Sigma Chemical, St Louis), followed by 0.5 mL of 6% trichloracetic acid, and after centrifugation for one minute, 0.5 mL of clear supernatant was mixed with 5 mL Aquasol (New England Nuclear) for liquid scintillation counting. The specific activity of ^{86}Rb in each suspension was determined by processing aliquots of the whole suspension and referred to the K^+ concentration in the media. The Hb content of the cell suspensions was measured by the cyanomethemoglobin method, and the RBC $^{86}Rb^+$ uptake was expressed as mmol/340 g Hb.

The ouabain-sensitive component of the K^+ ($^{86}Rb^+$) influx was calculated by subtracting, at each time point, the $^{86}Rb^+$ uptake in the presence of 10^{-4} mol/L ouabain from the uptake by ouabain-free control suspensions and plotting the values as a function of the external K^+ concentration ($[K^+]_0$).

In all cases the ouabain-sensitive $^{86}Rb^+$ influx was linear with time for at least 40 minutes. At a $[K^+]_0$ higher than 2 mmol/L, on the other hand, the ouabain-resistant influx was high at 0 °C and leveled off with time at 37 °C, becoming linear between 20 and 60 minutes. Slopes were drawn by eye over the linear portions of these curves and plotted as a function of $[K^+]_0$. The apparent affinity and V_{max} of the ouabain-sensitive influx were computed from a fit to Hill's equation[14] with n = 2.

Specific variations in the suspension media and in sampling times for the experiments shown in Fig 2 and Tables 1 and 2 are described in their legends

Measurement of RBC cation contents The total RBC Ca was measured by atomic absorption spectroscopy as described previously.[15] For determination of cell [Na] and [K], the cells were washed four times in 20 vol of ice-cold buffer containing (in mmol/L) $MgCl_2$, 108, and Tris-Cl, 10, pH 7.4 (20 °C), 291 mosm, and lysed in a 15-mmol/L LiCl solution, and [Na] and [K] were measured by flame photometry (Model 143, Instrumentation Laboratories, Lexington, Mass). The Hb content of an aliquot of each lysate was measured and the results expressed as mmol/340 g Hb.

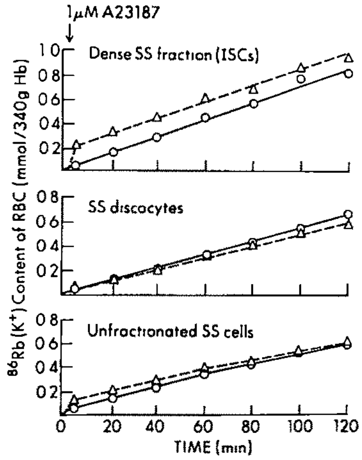

Fig 1. **Comparison of an active (ouabain-sensitive) and passive (ouabain-resistant) $^{86}Rb^+$ influx in density-fractionated SS discocytes and ISCs as a function of $[K^+]_0$. $[Na^+]_0$ was 150 − $[K^+]_0$. The following apparent kinetic parameters of the ouabain-sensitive $^{86}Rb^+$ influxes were obtained by plotting that data according to the logarithmic form of Hill's equation (see Materials and Methods): for the SS discocytes, K′ = 1.02, V_{max} = 2.1; for ISCs K′ = 1 10, V_{max} = 1.6.**

RESULTS

Features of experimental design. In attempting to detect a Ca^{2+}-dependent component of the passive K^+ ($^{86}Rb^+$) influx in SS cells, three experimental maneuvers were made. The basic maneuver was to expose an aliquot of each red cell sample to the ionophore A23187 in the presence of EGTA in the medium, which was shown to extract nearly all the excess Ca content of SS cells,[15] and to compare the ^{86}Rb influx in the Ca-containing and Ca-extracted cells. Most of the experiments we report here were performed on fractions of SS cells separated on Stractan density gradients. Since the dense, ISC-rich SS fraction was previously found

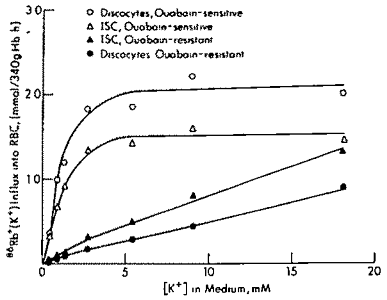

Fig 2. Effects of the removal of the endogenous cell Ca on the ouabain-resistant ^{86}Rb$^+$ influx in SS discocytes, ISCs, and unfractionated SS cells. RBCs were suspended at a 5% HCT value in media containing (in mmol/L) NaCl, 145; KCl, 5; Tris-Cl, 10, pH 7.7 (37 °C); Tris-EGTA, 1; MgCl$_2$, 0.2; glucose, 10; ouabain, 0.1; and 10 μCi/mL of ^{86}Rb. The ionophore A23187 was added from a 0.2 mmol/L solution in ethanol to give a final concentration of 1 μmol/L in the cell suspension. The percentage of lysis, determined at the end of the two-hour incubation by centrifugation and measurement of Hb concentration in the supernatant as compared with the total suspension Hb, was 3.4% and 3.3% for the unseparated cells in the absence and presence of ionophore, respectively: 1.6% and 2.8% for the discocytes; and 6.2% and 7.5% for the ISCs.

to have the highest Ca content,[5,6] the total Ca in the dense SS cell fraction from two donors was measured by atomic absorption spectroscopy before and after Ca extraction. In these samples, the total Ca contents in the dense cells were 89.0 and 71.0 μmol/340 g Hb, and after Ca extraction, 13.2 and 8.8 μmol/340 g Hb, respectively; this demonstrated that most of the excess Ca content in the ISC-rich fraction of cells was ionophore mobilizable, as observed previously in the unseparated SS cells.

Earlier analyses of the conditions for activation of the Ca^{2+}-dependent K$^+$ channel had suggested the possibility that the Ca sensitivity of the channel might be greater in ATP-depleted red cells than in fresh, substrate-fed cells.[16] Therefore, the ^{86}Rb$^+$ influx was measured in aliquots of ATP-depleted, Ca-containing and Ca-extracted red cells. Finally, as an additional condition for the ATP-depleted cells, we tested the effect of quinine, a known inhibitor of the Ca^{2+}-sensitive K$^+$ channel.[11] Since the combined addition of quinine and ouabain have been observed to produce complex effects on ion transport,[4] ouabain was omitted in cell suspensions receiving quinine additions and in the corresponding control suspension.

Table 1. Effects of Ca Extraction, ATP Depletion, and Quinine on Passive ^{86}Rb$^+$ Influx in Red Cells Incubated in High-K$^+$ Media

	^{86}Rb Influx (mmol/L RBC/hr)					
	AA Red Cells		SS Red Cells			
		ATP-Depleted		ATP-Depleted		
	Fed Ouabain	ATP-Depleted Ouabain	Fed Ouabain	Ouabain	Control	Quinine
Ca present	4 2	3 8	8 8, 5 8	8 4	7.7	8 0
Ca extracted	4 4	4 8	10 0, 7.2	8 7	8.4	7 6

RBCs were incubated in media containing (in mmol/L) KCl, 75; NaCl, 75, Tris-phosphate, 10, pH 7 5 (37 °C), Tris-EGTA, 0.1, and 10 μCi/mL of ^{86}Rb$^+$ Samples were taken at zero time (at 0 °C) and at 2, 4, 6, 10, 15, 20, 25, and 30 minutes' incubation at 37 °C and processed as described in Materials and Methods A high initial (zero time) uptake was seen with the Ca-extracted fed cells and especially with the ATP-depleted, Ca-extracted cells and was attributed to a small number of very leaky cells produced during these manipulations that equilibrated with the external ^{86}Rb$^+$ in the cold. Subsequent ^{86}Rb$^+$ uptake was linear in all samples over the 30-minute incubation period, and influx values were obtained from the slopes of lines drawn by eye through the data points When present, the concentration of ouabain was 0 1 mmol/L and of quinine, 1 mmol/L.

Passive ^{86}Rb influx in unfractionated normal and SS RBCs. Table 1 compares the passive ^{86}Rb influx in unfractionated normal and SS cells incubated in a high-K$^+$ (75 mmol/L) medium. For each condition, the ^{86}Rb$^+$ influx in the SS cells was higher than that in normal red cells (generally by about twice). But neither Ca extraction alone nor the additional procedures of ATP depletion or quinine addition revealed any indication of a Ca^{2+}-activated K$^+$ leak.

Passive ^{86}Rb$^+$ influx in density-fractionated SS RBCs Subsequent experiments were performed with density-fractionated SS cells, comparing the reticulocyte-free discocytes and the dense, ISC-rich fractions. In this group of experiments, the cells were suspended in a low-K$^+$ (5 mmol/L) medium in which any activation of the Ca^{2+}-dependent K$^+$ channel would increase the membrane potential, resulting in a proportionately larger influx of ^{86}Rb$^+$ by the countertransport mechanism.[17]

Figure 2 shows an experiment comparing the ^{86}Rb$^+$ influx in suspensions of SS discocytes, ISCs, and unfractionated SS cells. The addition of ionophore A23187 (with excess EGTA in the medium) to a parallel aliquot of each suspension caused a sharp transient increase in the ^{86}Rb$^+$ influx that was barely detectable in the discocytes and maximal in the ISCs When this response to ionophore exposure was described earlier with unfractionated SS cells,[4] it was found to be inhibited by quinine; it was therefore interpreted as an ionophore-mediated increase in the apparent affinity of the K channel for endogenous Ca, either by a direct action of the ionophore on the Ca affinity of the activation site or by its facilitating the access of Ca to the site. The new detail seen here is that the magnitude of the ionophore effect is highest in ISCs, which are also known to contain the highest Ca content.[5,6] Following this transient initial effect, however, Ca extraction had only a minimal inhibitory effect on the two-hour ^{86}Rb influx When similar experiments were performed comparing discocytes and ISCs, experiments in which the endogenous Ca was either left in the cells or was extracted with ionophore and EGTA, washing away the ionophore before the incubation, Ca extraction showed no effect on the ^{86}Rb$^+$ influx (Table 2).

Additional results in Table 2 show the passive ^{86}Rb$^+$ influx, with SS discocytes and ISCs suspended in low-K$^+$ media, under each of the conditions used to try to reveal a possible Ca^{2+}-dependent K$^+$ flux. Although some of the maneuvers were associated with small changes in the ^{86}Rb$^+$ influx, the changes bore no consistent relation to Ca extraction procedures. It is particularly noteworthy that in the dense, ISC-rich SS cell fraction, known to have the highest Ca content, neither Ca extraction nor quinine addition produced a significant decrease in ^{86}Rb$^+$ influx, and the

Table 2. Effects of Ca Extraction, ATP Depletion, and Quinine on Passive $^{86}Rb^+$ Influx in Density-Fractionated SS Red Cells Incubated in Low-K^+ Media

	^{86}Rb Influx (mmol/340 g Hb/hr)

Ca extracted	0.40, 0.28*	0.49	0.48	0.70	0.40, 0.40*	0.40	0.36	0.58

*Values were derived from the experiment illustrated in Fig 2 in which there were minor differences in the composition of the suspension media (see legend of Fig 2) and the ionophore was added to parallel suspensions after the start of the incubation to extract the cell Ca

RBCs were incubated in media containing (in mmol/L) KCl, 5, NaCl, 140, Tris-phosphate, 10, pH 7.5 (37 °C); Tris-EGTA, 0.1; and 10 μCi/mL of $^{86}Rb^+$. $^{86}Rb^+$ influx was determined as described in the legend of Table 1.

influx was not increased in the Ca-containing cells by ATP depletion.

Active and passive $^{86}Rb^+$ influx as a function of $[K^+]_0$. Measurement of the ouabain-sensitive and ouabain-resistant $^{86}Rb^+$ influx in SS discocytes and ISCs as a function of $[K^+]_0$, illustrated in Fig 1, shows that the passive K^+ ($^{86}Rb^+$) influx of the discocytes fell within a normal range,[18] whereas the ISC fraction showed an increased passive influx of $^{86}Rb^+$ that was nonsaturable over this range of $[K^+]_0$. The saturable component of the ouabain-resistant $^{86}Rb^+$ influxes, plotted separately after subtraction of the nonsaturable linear components[13] (not illustrated), was not significantly different for the discocytes and ISCs. In the experiment in Fig 1 and another similar experiment, Na pump activity, as estimated by ouabain-sensitive $^{86}Rb^+$ influx (expressed in relation to $[K^+]_0$), appeared normal in the SS discocytes ($K' = 1.02$ and 0.98; $V_{max} = 2.1$ and 2.2 mmol/340 g Hb/hr) but was inhibited in the ISC fraction, which showed normal K' values of 1.10 and 0.94 but reduced V_{max} values of 1.6 and 1.4 mmol/340 g Hb/hr

Effect of Ca extraction on active $^{86}Rb^+$ influx. In another experiment (not illustrated), ouabain-sensitive $^{86}Rb^+$ influx was measured in discocyte and ISC fractions, with an aliquot of each fraction having first been incubated with ionophore A23187 and EGTA to extract the endogenous Ca. With $[K^+]_0$ at 10 mmol/L to fully saturate the pump with K^+, the $^{86}Rb^+$ influx was 3.4 mmol/340 g Hb/hr for the discocytes and 1.0 mmol/340 g Hb/hr for the ISC fraction. Ca extraction produced no change in either value, indicating that the marked Na pump inhibition found with the ISC fraction was not corrected by removal of their excess Ca content.

DISCUSSION

The findings described here demonstrate that neither the discocyte SS cells nor the dense ISC-rich fraction, whose total Ca content generally exceeds 100 μmol/L RBCs,[5,6] show a sustained Ca^{2+}-dependent component of the passive K^+ ($^{86}Rb^+$) flux whether the cells are metabolically replete or ATP depleted.

The various predicted consequences of the established high Ca content of SS red cells, including dehydration resulting from Ca^{2+} activation of the K^+ channel,[2,3] have presumed that much if not all the excess Ca found in these cells is freely distributed in their cytoplasm If this were so, then since SS cells have been found to show cytoplasmic Ca^{2+} buffering in the normal range with a 20% to 30% ionized fraction,[15] a mean total Ca content of 40 to 60 μmol/L RBCs[15,19,20] would indicate a cytoplasmic-free ionized Ca^{2+} content of 8 to 18 μmol/L, and in the ISCs, whose total Ca content may be 100 to 200 μmol/L RBCs or more,[5,6] a Ca^{2+} of more than 20 μmol/L. Measurements of the $^{86}Rb^+$ influx in ATP-depleted normal red cells show maximal activation of the Ca^{2+}-sensitive channel above 4 μmol/L $[Ca^{2+}]_i$, with half-maximal activation around 2 μmol/L $[Ca^{2+}]_i$.[21] Levels of 1 μmol/L $[Ca^{2+}]_i$ or less in the SS cells should have produced a substantial and easily measurable increase in the $^{86}Rb^+$ influx in the SS cells. Failure to detect any Ca^{2+}-sensitive $^{86}Rb^+$ influx, even in the ISC fraction, would appear to indicate either a refractory state of the K^+ channel, which contradicts available evidence,[3,4] or compartmentalization of the Ca in SS cells in a manner that prevents its access to the inner surface of the cell membrane. Our earlier findings of the failure of SS cells to extrude much of the Ca accumulated during sickling or by ionophore loading, despite minimal abnormalities in the membrane Ca^{2+}-Mg^{2+}ATPase together with very low exchange rates of the endogenous Ca with external ^{45}Ca[15] and our initial observations of no quinine-sensitive K^+ leak in unfractionated SS cells,[4] led us to postulate that the excess Ca in these cells is compartmentalized in endocytic inside-out vesicles (EIOVs).[22] We have recently provided direct evidence to substantiate this hypothesis,[23] showing that SS cells contain vesicles that are capable of ATP-dependent Ca accumulation against an outward gradient and that the vesicles contain very high concentrations of Ca, probably in the form of precipitates with phosphates (which must be easily dissolved and extracted during brief exposure to the ionophore A23187 and EGTA).

The present findings are consistent with the compartmentalization of SS cell Ca in EIOVs. Immediately following exposure of the cells to ionophore while the Ca is being mobilized out of the vesicles and through the cytoplasm, there is transient activation of the Ca^{2+}-sensitive K^+ channel, as seen in Fig 2.

Partial inhibition of the Na pump in ISCs, as first observed by Clark et al,[7] is shown here to be characterized by normal sensitivity to $[K^+]_0$ but a low V_{max}, which is particularly abnormal in view of the elevated Na^+ concentrations in ISCs.[24,25] Clark et al found normal ATP concentrations in the

ISCs[24] as well as normal Na^+-K^+ ATPase activities in their membranes,[7] and it seemed possible that the Na pump inhibition observed in the intact ISCs might result from their high Ca content. We have shown here that the reduction in the V_{max} of the $^{86}Rb^+$ influx of the ISCs persists after extraction of their excess Ca with ionophore and EGTA. Brown and Lew[8] have found that a persistence of Na pump inhibition in red cells exposed to ionophore and Ca^{2+} is associated with an irreversible reduction in the ATP content of those cells. In view of the normal ATP concentrations found in ISCs, the persistence of Na pump inhibition after Ca extraction suggests that the increased cell Ca is not responsible for the inhibition. This interpretation is also consistent with compartmentalization of the SS Ca. If Ca had been involved in Na pump inhibition, its effects must have been irreversible and not mediated by ATP depletion.

Although the sickle cells showed no evidence of an ongoing Ca^{2+}-sensitive K^+ leak, the ouabain-resistant component of the $^{86}Rb^+$ influx, although of normal magnitude in the SS discocytes, was clearly increased in the dense, ISC-rich fraction of SS RBCs. This increase was shown to be limited to the unsaturable electrodiffusional component of the passive $^{86}Rb^+$ influx since it increased linearly with $[K^+]_0$ over the range observed. With the high outward K^+ gradient in RBCs, this increased Ca^{2+}-independent passive K^+ leak could be substantial and, if uncompensated, could contribute to the cell dehydration observed with ISCs

This finding of an increase only in the nonsaturable component of the $^{86}Rb^+$ influx of ISCs may help explain the apparent discrepancy in the results of Clark et al,[7] who described a normal passive $^{86}Rb^+$ influx in the ISCs despite an increase in the passive K^+ efflux. This increase in the K^+ efflux was similarly high in the middle and bottom SS cell density fractions when expressed as a function of the mean cell $[K^+]$ (as a rate constant). Their passive $^{86}Rb^+$ influx measurements were made at $[K^+]_0$ concentrations of 5 mmol/L, conditions under which we found little or no differences between discocytes, ISCs, and normal reported values. Our findings of an increased nonsaturable passive $^{86}Rb^+$ influx in the ISCs, which was greater than that in the discocytes, is also compatible with the observation of Clark et al of similar rate constants of a passive K^+ efflux for middle and bottom SS cell fractions since a greater leakiness in the dense cells would be counterbalanced by the lower cell $[K^+]$ in that fraction.

The absence of evidence of Ca^{2+}-sensitive K^+ channel activity in oxygenated SS cells does not exclude the possibility that transient small increases in cytoplasmic-free Ca^{2+}, which might occur during periods of increased Ca permeability associated with deoxygenation-induced Hb S polymerization and RBC sickling, could briefly activate K^+ channels in some cells, thereby contributing to their dehydration. The findings of Ohnishi[26] of an apparent Ca^{2+} dependence of the formation of dense cells during cycles of deoxygenation and oxygenation of SS cells in vitro provides some indirect evidence for such a mechanism.

Hemoglobin Switching During Murine Embryonic Development: Evidence for Two Populations of Embryonic Erythropoietic Progenitor Cells

By Peter M.C. Wong, Siu-Wah Chung, Susan M. Reicheld, and David H.K. Chui

Explants of normal mouse embryonic tissues and disaggregated embryonic single cells were cultured in vitro to study the erythropoietic progenitor cells present during embryonic development. The results indicate that there are two populations of erythropoietic progenitor cells committed to different hemoglobin synthetic programs. These progenitor cells are present at an early gestational stage prior to the formation of the fetal hepatic primordium. One population of progenitors can be stimulated by erythropoietin alone to form usually small erythroid colonies after culture for six days in vitro. These erythroblasts primarily synthesize embryonic hemoglobins, but produce some adult hemoglobins as well. The other population of progenitors requires stimulation by both erythropoietin and adult spleen cell–conditioned medium, and usually forms large erythroid colonies after culture for six days in vitro. These erythroblasts produce only adult hemoglobins.

ERYTHROPOIESIS during normal murine embryogenesis provides an excellent model system to study the developmental cell biology of hemoglobin switching. The circulating primitive erythrocytes, derived from yolk sac blood islands, proliferate and mature in a relatively synchronized manner. These primitive erythrocytes synthesize embryonic hemoglobins as well as some adult hemoglobins.[1-7] On day 9 of gestation, there are hematopoietic progenitor cells in the yolk sac and the embryonic circulation that, in culture, give rise to erythroblasts synthesizing adult hemoglobins.[8,9] From day 11 on, the fetal hepatic erythroblasts as well as the erythropoietic progenitor cells in the fetal livers are committed to adult hemoglobin synthesis.[10] In this study we have cultured embryonic tissues and disaggregated embryonic single cells on day 8 of gestation to document clearly the presence of different populations of erythropoietic progenitor cells during embryonic development.

The results indicate that on day 8 of gestation prior to the formation of the fetal hepatic primordium, there are two populations of erythropoietic progenitor cells. The first detectable population of progenitor cells, when cultured in vitro with erythropoietin alone for six days, usually give rise to small erythroid colonies containing erythroblasts that synthesize primarily embryonic hemoglobins but produce some adult hemoglobins as well. Addition of adult spleen cell–conditioned medium has no demonstrable effect upon the growth of these erythroid colonies. Shortly after, another population of progenitor cells were detected that, when cultured in vitro with both erythropoietin and adult spleen cell–conditioned medium for six days, usually produce large erythroid colonies synthesizing only adult hemoglobins

MATERIALS AND METHODS

Tissues and cells. Normal adult FL/4Re inbred mice obtained from the Jackson Laboratory, Bar Harbor, Me, were mated, and the morning on which the vaginal plug was found was designated as day 0 of gestation At approximately six-hour intervals on day 8 of gestation, embryos with their intact extraembryonic membranes were carefully dissected and washed free of maternal tissues and blood cells They were placed in methylcellulose culture medium[10] and cut into small fragments (<0 5 mm) before culture. On days 9 and 10 of gestation, only the yolk sacs were dissected free and cut into similarly small fragments for culture.

For disaggregated embryonic single cells, normal Balb/c mice obtained from the Cumberland View Farms (Clinton, Tenn) were mated as was described. Around noon on day 8 of gestation, embryos with their extraembryonic membranes were dissected free, washed, and digested with collagenase (Sigma Chemical Co, St Louis) at a final concentration of 0 1% in phosphate-buffered saline without calcium and magnesium but with 20% fetal calf serum (Flow Laboratories, McLean, Va) for three hours at 37 °C with intermittent agitation. At the end of the incubation, the digestion mixture was allowed to settle for five minutes, and the supernatant containing disaggregated embryonic single cells was harvested. Each day-8 conceptus would yield approximately 1 to 5 × 10^4 cells

Erythroid cell cultures Embryonic tissue fragments were cultured in methylcellulose culture medium at 37 °C for six to eight days as described previously.[10] Erythropoietin (Connaught Laboratories, Toronto; specific activity, 2 to 4 U/mg of protein) was added to these cultures, usually at 1 to 2 U/mL. Adult spleen cell–conditioned medium was prepared from C57BL/6J mice and was added to account for 20% of the erythroid cultures.[9]

Cultures of disaggregated embryonic cells were done similarly except that the spleen cell–conditioned medium was prepared according to the method of Eaves et al[11] and was added to account for 1.25% of the culture Erythropoietin was added to the cultures at a final concentration of 2 to 3 U/mL. A quantity of 1 to 3 × 10^4 cells was plated in 0.7 mL of culture medium

Hemoglobin analysis Hemolysates of the erythroblasts harvested from the cultures were analyzed by thin-layer isoelectric focusing and stained with benzidine dihydrochloride (Sigma) and scanned by a Beckman densitometer (Beckman Instruments, Inc, Burlington, Vt).[10]

For immunocytochemical studies, individual in vitro erythroid colonies were carefully picked by means of a micropipette. They were deposited on glass slides, immediately air dried, and fixed in acetone/methanol They were subsequently stained with rabbit

anti-HbA antibodies conjugated with fluorescein and rabbit anti-HbE antibodies conjugated with rhodamine.[10] After washing, the slides were examined in a Zeiss microscope equipped for reflected light–fluorescence microscopy.

RESULTS

Cultures of embryonic tissue fragments. Early on day 8 of gestation, hemoglobinized cells were not observed in the embryonic tissues in situ. Cultures of small fragments of these early day 8 embryonic tissues and extraembryonic membranes in vitro for six to eight days with added erythropoietin produced clusters of well-hemoglobinized erythroblasts, each consisting of approximately 100 to 200 erythroid cells. All three embryonic hemoglobins (E1, x_2y_2; E11, α_2y_2; and E111, α_2z_2) were present in these cultures, but adult hemoglobins ($\alpha_2\beta_2^{\mathrm{dmaj}}$ and $\alpha_2\beta_2^{\mathrm{dmin}}$) were not detected by the isoelectric-focusing technique (Fig 1). The further addition of adult spleen cell–conditioned medium to these cultures did not alter the erythroid growths or the types of hemoglobins produced as determined by the isoelectric-focusing technique (Fig 1).

Cultures of day 8½ embryonic tissues and extraembryonic membranes with added erythropoietin produced more prominent erythroid growth. The hemoglobins produced were primarily embryonic hemoglobins, but some adult hemoglobins were also detected (Figs 1 and 2). Immunocytologic study revealed that virtually all the erythroblasts in the cultures contained both embryonic and adult hemoglobins (Figs 3A and 3B). When both erythropoietin and adult spleen cell conditioned–medium were added to the cultures of day 8½ embryonic tissues and extraembryonic membranes, there were some macroscopic erythroid bursts reminiscent of the bursts seen in cultures of days 9 to 12 embryonic peripheral blood cells[9] in addition to the well-hemoglobinized erythroid cell clusters. Both embryonic and adult hemoglobins were produced in these cultures, and the proportion of adult hemoglobins synthesized was much augmented compared to the cultures with only erythropoietin added (Figs 1 and 2). Immunocytologic study revealed that, in addition to erythroblasts containing both embryonic and adult hemoglobins, there were also many erythroblasts containing only detectable adult hemoglobins (Figs 3C and 3D).

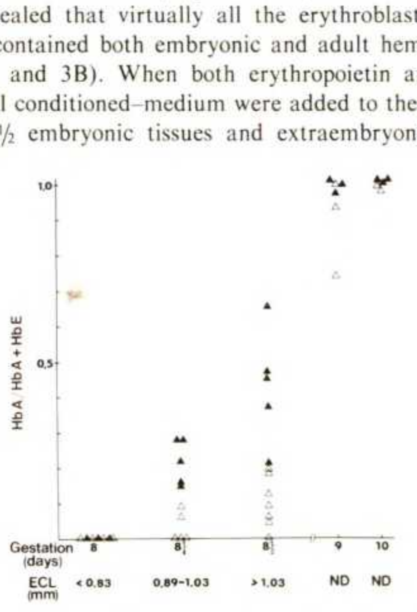

Fig 1. Proportion of HbA synthesized in cultures of fragments of FL/4Re day-8 embryonic tissues and extraembryonic membranes as well as day-9 and day-10 yolk sacs. The methylcellulose cultures were incubated for six to eight days. The hemolysates of the erythroblasts harvested at the end of the cultures were analyzed by thin-layer isoelectric-focusing and scanned by a Beckman densitometer. Each symbol represents an individual culture. (△) Cultures with only erythropoietin (Ep) added, usually at a final concentration of 2 U/mL of culture. Fig 2. Isoelectric focusing of hemoglobins stained with benzidine dihydrochloride. Lanes 1 and 5, hemolysate of FL/4Re day-12 peripheral blood. Most of the erythrocytes are yolk sac blood island–derived primitive erythrocytes containing primarily embryonic hemoglobins in addition to a small amount of adult hemoglobins.[5] Lane 2, hemolysate from the culture of fragments of FL/4Re day-8½ embryonic tissues and extraembryonic membranes with only erythropoietin added. Note that there is a faint band of adult major hemoglobin in addition to that of embryonic hemoglobins. Lanes 3 and 4, hemolysates from similar cultures as in lane 2 except that both erythropoietin and adult spleen cell conditioned–medium were added. The conditioned media used were from two different perparations. Note that there are prominent bands of adult major hemoglobin in addition to that of embryonic hemoglobins.

On days 9 and 10 of gestation, the yolk sacs with many hemoglobinized primitive nucleated erythroblasts present within the vasculature were dissected free of maternal tissues and the embryo proper. These yolk sacs were further cut into small pieces and cultured. Almost all of the hemoglobins detected in these cultures were adult hemoglobins (Fig 1). Moreover, the erythroid growth was much more prominent in the cultures to which both erythropoietin and adult spleen cell–conditioned medium had been added, as has been previously reported.[9] That the cultures of days 9 or 10 yolk sac fragments produced adult hemoglobins and not embryonic hemoglobins indicates that the erythroid cell growth in the cultures after six to eight days in vitro represents the progeny of erythroid progenitor cells and not the terminal maturation of circulating primitive erythroblasts.

Cultures of disaggregated embryonic cells. Day 8½ embryonic tissues and extraembryonic membranes were digested with collagenase in the presence of 20% fetal calf serum, and single-cell suspensions were obtained. These

single cells could form erythroid colonies in vitro under the appropriate culture conditions (Table 1). Erythroid colonies were not observed in cultures to which erythropoietin and adult spleen cell conditioned-medium were not added. Erythropoietin alone stimulated the growth of many small erythroid colonies when examined after six days in culture. Adult spleen cell conditioned-medium alone produced a few small as well as large erythroid colonies. However, in cultures with both erythropoietin and adult spleen cell-conditioned medium added, there were a significant number of large erythroid colonies in addition to numerous small erythroid colonies (Table 1).

Twelve small erythroid colonies were picked from cultures in which only erythropoietin was added. These were examined by the immunocytochemical technique, and all were found to consist of erythroblasts containing both embryonic and adult hemoglobins (Table 2). On the other hand, in cultures with both erythropoietin and adult spleen cell conditioned-medium added, seven erythroid colonies, four small and three large or mixed colonies, were found to be made up

Table 1. Erythroid Colonies in Cultures of Disaggregated Embryonic Single Cells on Day 8½ of Gestation

Balb/c embryonic tissues and extraembryonic membranes on day 8½ of gestation were digested with collagenase in the presence of 20% fetal calf serum to obtain disaggregated embryonic single cells. The average egg cylindrical lengths of these embryos vary between 1.0 and 1.4 mm. A quantity of 2 to 4 × 10^4 cells/mL were plated in methylcellulose and cultured for six days. Colonies were enumerated under an inverted microscope without staining. Data are expressed as mean numbers of colonies per 5 × 10^4 nucleated cells plated per experiment. For each experiment, two to four methylcellulose cultures were done.

Table 2. Immunocytochemical Studies of Individual Erythroid Colonies Picked From Cultures of Disaggregated Embryonic Single Cells on Day 8 of Gestation

Experiment	Erythropoietin (2-3 U/mL)	Adult Spleen Cell-Conditioned Medium (1.25%)	Erythroid Colonies, No.		
			EA	A and EA	A
A	Yes	No	8	0	0
	Yes	Yes	2	2	4
B	Yes	No	4	0	0
	Yes	Yes	5	0	3

Disaggregated single cells of Balb/c embryonic tissues and extraembryonic membranes on day 8 of gestation were cultured in methylcellulose for six days. The average egg cylindrical lengths of the embryos used in experiments A and B were 0.9 and 1.2 mm, respectively. Individual erythroid colonies were carefully picked with a micropipette under an inverted microscope, deposited on slides, air dried, fixed, and double stained with monospecific anti-HbA antibodies conjugated with fluorescein and anti-HbE antibodies conjugated with rhodamine. Abbreviations: EA, erythroid colonies made up of erythroblasts containing both embryonic and adult hemoglobins as detected by the immunocytochemical technique; A and EA, erythroid colonies made up by many erythroblasts containing only demonstrable HbA and some other erythroblasts containing both embryonic and adult hemoglobins; A, erythroid colonies made up of erythroblasts containing only demonstrable HbA. See text for details.

of cells containing both embryonic and adult hemoglobins (Table 2 and Figs 4A and 4B). Seven other erythroid colonies, one small and six large or mixed colonies, were made up of cells containing only detectable adult hemoglobins (Table 2 and Figs 4C and 4D). There were two other large or mixed erythroid colonies that were made up of erythroblasts containing both embryonic and adult hemoglobins as well as erythroblasts containing adult hemoglobins only (Table 2).

These data are suggestive that on day 8½ of gestation there is a population of erythropoietic progenitor cells that give rise usually to small erythroid colonies after culture in vitro for six days with erythropoietin. The erythroblasts derived from these progenitor cells synthesize primarily embryonic hemoglobins, but produce some adult hemoglobins as well, similar to the yolk sac–derived primitive erythroblasts in vivo.[5] In addition, there is another population of erythropoietic progenitor cells that needs to be stimulated by both adult spleen cell–conditioned medium and erythropoietin to form usually large erythroid colonies after culture for six days in vitro. These erythroblasts produce only adult hemoglobins, similar to the fetal liver–derived erythroblasts in vivo.[10]

DISCUSSION

It has been proposed that there are two cell lineages in mammalian embryonic erythropoiesis committed to different hemoglobin synthetic programs.[12,13] The results of the present study support such a concept. Moreover, these studies show that the erythropoietic progenitor cells, capable of giving rise to progeny synthesizing primarily embryonic hemoglobins as well as progenitor cells committed to adult hemoglobin production, are detected on day 8 of gestation, prior to the appearance of the fetal hepatic primordium. A model of normal murine embryonic erythropoiesis is proposed and illustrated in Fig 5.

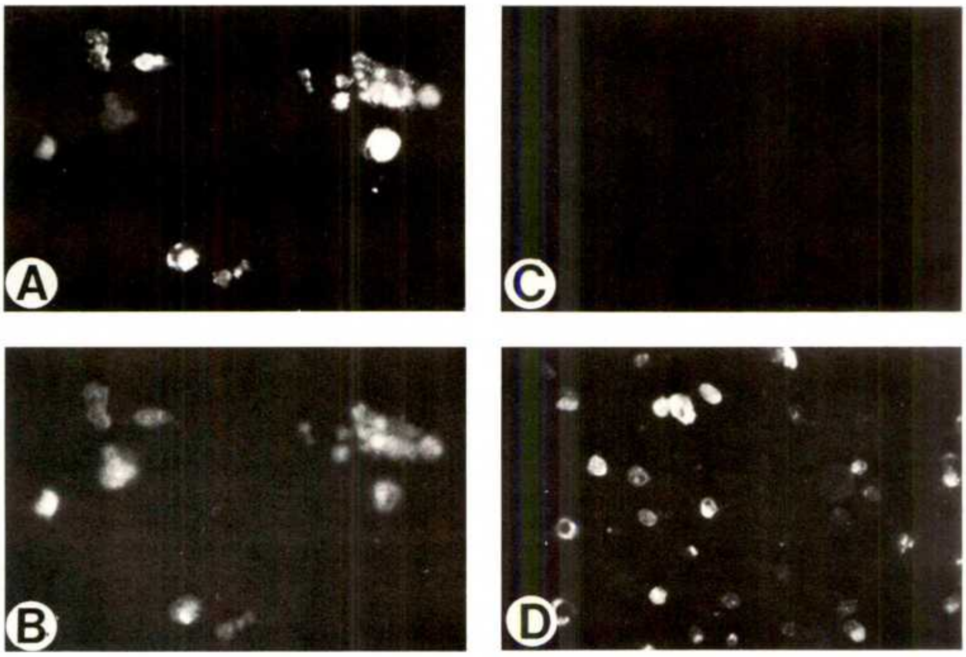

Fig 4. Immunocytologic studies of erythroblasts harvested from individual colonies in cultures of Balb/c disaggregated single-cell suspension of day-8 embryonic cells. Both erythropoietin and adult spleen cell–conditioned medium were added to these cultures. Original magnification × 380; current magnification × 304. (A and B) Small erythroid colony estimated to consist of less than 300 erythroblasts. (A) Immunofluorescence of rhodamine-conjugated anti-HbE. (B) Immunofluorescence of fluorescein-conjugated anti-HbA. Note that all the cells contain both HbE and HbA. (C and D) Large erythroid burst colony. (C) Immunofluorescence of rhodamine-conjugated anti-HbE. (D) Immunofluorescence of fluorescein-conjugated anti-HbA. Note that all the cells contain only detectable HbA.

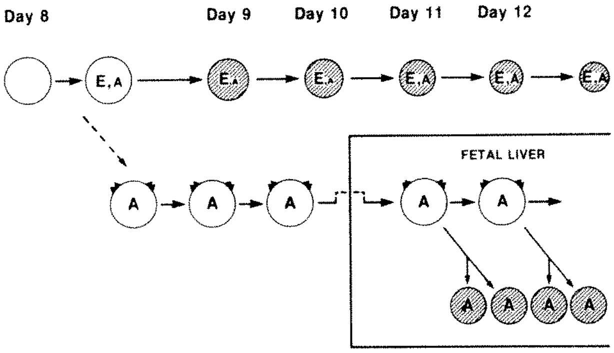

Fig 5. A model of normal murine embryonic erythropoiesis. See text. Key: ○, erythroid progenitor cells committed to the synthesis of either HbE and some HbA, or HbA; ●, Hemoglobinized erythroblasts containing either HbE and some HbA, or HbA; ▲▲, receptor for the putative mitogenic factor(s) present in the adult spleen cell–conditioned medium; ------, path not yet proven experimentally.

The first population of erythropoietic progenitor cells is found early on day 8 of gestation. More recently, we were able to detect similar erythropoietic progenitor cells by culturing disaggregated embryonic cells of day 7 of gestation. These progenitor cells usually form small erythroid colonies after culture for six days in vitro with erythropoietin alone. Adult spleen cell–conditioned medium does not have a demonstrable effect upon them. The erythroblasts in the erythroid colonies derived from these progenitor cells obtained from early day 8 embryos produced embryonic hemoglobins demonstrable by isoelectric focusing (Fig 1). It is conceivable that a very minute amount of adult hemoglobins are also present in these erythroblasts but not detectable by the comparatively less-sensitive isoelectric-focusing technique. By mid to late day 8 of gestation, these progenitor cells give rise to erythroid colonies that can be shown clearly to synthesize mostly embryonic hemoglobins but some adult hemoglobins as well, as shown by the isoelectric-focusing technique (Figs 1 and 2) and immunocytochemistry (Figs 3A, 3B, 4A, and 4B). By day 9, these erythroid progenitor cells are not found either in the yolk sac or in the embryonic circulation.[8,9]

Later, on day 8 of gestation, another population of erythropoietic progenitor cells appears whose progeny are committed to adult hemoglobin synthesis (Fig 4C and 4D). These progenitor cells are responsive to stimulation by the adult spleen cell–conditioned medium and erythropoietin (Figs 1 and 2). It is likely that the factor(s) present in the adult spleen cell–conditioned medium stimulates cellular proliferation and differentiation of erythropoietic progenitor cells already committed to adult hemoglobin synthesis. This hypothesis is supported by the following observations. First, the adult spleen cell–conditioned medium does not alter the types of hemoglobins produced in cultures of early day 8 embryonic tissues (Fig 1). Second, in the cultures of late day 8 embryonic tissues with both erythropoietin and adult spleen cell–conditioned medium added, there were in addition to the small erythroid colonies large erythroid bursts that were rarely seen in the cultures with only erythropoietin added (Table 1). Last, most of these large erythroid colonies that were found in cultures to which both adult spleen cell–conditioned medium and erythropoietin were added consisted of erythroblasts containing only adult hemoglobins demonstrable by immunocytochemistry (Fig 4C and 4D). Thus, the emergence of progenitor cells committed to adult hemoglobin synthesis is accompanied also by the appearance of receptors for the putative mitogenic factor(s) present in the adult spleen cell–conditioned medium. More definitive studies are required to rule out the other possibility that the adult spleen cell–conditioned medium has a direct effect upon the hemoglobin synthetic program of murine embryonic erythropoietic progenitor cells.

Many of the biologic activities ascribed to the adult spleen cell–conditioned medium have been found to be due to interleukin 3 (IL-3) present in the conditioned medium.[14,15] It should be informative to determine whether purified IL-3 preparation can replace the adult spleen cell–conditioned medium in stimulating the proliferation and differentiation of murine embryonic erythropoietic progenitor cells committed to adult hemoglobin synthesis. We have previously shown that embryonic fluid obtained from the exocoelom of day 10 embryos could induce the erythroid colony growths in vitro from circulating embryonic hematopoietic progenitor cells, and these erythroblasts in vitro synthesize only adult hemoglobins.[9] A recent report suggests that mouse yolk sacs can produce factors capable of inducing large erythroid colonies in vitro.[16] The nature and the mechanism of action for these activities remain to be clearly defined.

In cultures of day 8 disaggregated embryonic cells with both erythropoietin and adult spleen cell–conditioned medium added, 14 out of a total of 16 individual erythroid colonies examined were found to consist of either erythroblasts containing only adult hemoglobins or erythroblasts containing both embryonic and adult hemoglobins, as shown by the immunocytochemical technique (Table 2). The specificity of the antibodies used has been previously reported.[10] The sensitivity of the immunocytochemical technique has not been quantitatively determined. However, in a recent publication, the results obtained by the immunocytochemical studies were clearly corroborated by two different experimental approaches.[10] In the same cultures, there were two large erythroid colonies, each of which was found to consist of erythroblasts containing only adult hemoglobins and erythroblasts containing both embryonic and adult hemoglobins. It is conceivable that each of these two erythroid colonies was derived from two different erythroid progenitor cells that happened to be in close proximity to each other when first plated. Alternatively, these observations may indicate the presence of some embryonic erythropoietic progenitor cells with bipotentiality with regard to their commitment to the hemoglobin synthetic programs.

Beginning on day 9 of gestation, the erythropoietic progenitor cells committed to adult hemoglobin synthesis are found in the yolk sac and in the embryonic circulation (Fig 1) as has been previously reported.[8,9] From day 11 on, the fetal hepatic erythropoietic progenitor cells as well as the fetal hepatic erythroblasts are committed to adult hemoglobin synthesis also.[1-3,10] It is therefore probable that the circulating progenitor cells are responsible for the seeding of the fetal liver on days 10 and 11 of gestation to initiate fetal hepatic erythropoiesis, although direct and definitive experimental evidence is not yet available.

The first population of murine embryonic erythropoietic progenitor cells can be clearly detected early on day 8 of gestation. They respond to the stimulation of erythropoietin in culture and give rise usually to small erythroid colonies. Their erythroblasts produce both embryonic and adult hemoglobins. By day 9 of gestation and thereafter, these progenitor cells can no longer be detected.[8,9] On the other hand, the second population of progenitor cells was detected beginning later on day 8 of gestation. Their proliferation and differentiation in vitro require stimulation by both erythropoietin and spleen cell–conditioned medium. Usually they give rise to large or mixed erythroid colonies, and their erythroblasts synthesize only adult hemoglobins. The interrelationship of these two populations of embryonic erythropoietic progenitor cells is presently unknown. They may arise independently, or the progenitor cells committed to adult hemoglobin synthesis may evolve directly from the progenitor cells committed primarily to embryonic hemoglobin synthesis but producing some adult hemoglobins as well.

ACKNOWLEDGMENT

We thank Dr C.J. Eaves for her interest and advice during the latter part of this investigation.

Characterization of Natural Killer Cells With Antileukemia Activity Following Allogeneic Bone Marrow Transplantation

By Thierry Hercend, Tak Takvorian, Alexandre Nowill, Ramana Tantravahi, Philippe Moingeon, Kenneth C. Anderson, Christine Murray, Claude Bohuon, Arnaud Ythier, and Jerome Ritz

To identify cells with potential antileukemia activity following bone marrow transplantation, we have monitored immunologic reconstitution in a patient with acute lymphocytic leukemia in second remission who received intensive chemotherapy and total body irradiation followed by infusion of allogeneic histocompatible marrow. Prior to transplantation, donor bone marrow cells were depleted of T lymphocytes by in vitro treatment with anti-T12 monoclonal antibody and rabbit complement. In the first 3 weeks following bone marrow transplantation, the predominant regenerating mononuclear cell population in peripheral blood exhibited a phenotype characteristic of natural killer (NK) cells. After 4 weeks, T lymphocytes became predominant, but NK cells persisted. Cultured peripheral blood lymphocytes obtained 12 weeks posttransplant were able to display significant cytotoxicity against leukemic blasts that had been cryopreserved at the time of relapse 5 months prior to bone marrow transplantation. To further characterize those cells with antileukemia activity, we used in vitro cloning techniques to identify four monoclonal populations, termed TC12, -48, -50, and -59, with strong antitumor activity. Cytogenetic analysis demonstrated that each clone was of donor origin. Phenotypic characterization showed that the four clones expressed NKH1$_A$ but did not express T3, T4, or T8 antigens. Three of the four clones expressed T11/E rosette antigen. Each clone exhibited strong cytotoxicity against genetically unrelated hematopoietic tumor cell lines such as K562, Molt-4, JM, and U937. In addition, we found that these patient clones were similar to cloned NK cells previously derived from normal individuals. Taken together, these results suggest that at least some clones with antileukemia activity following bone marrow transplantation are cells with NK-like function and phenotype. Functional analysis of these cytolytic cells in larger numbers of patients will be necessary to determine the clinical significance of this finding.

WITHIN the last 10 years intensive chemotherapy and total body irradiation (TBI) followed by transplantation of allogeneic bone marrow has become established as an effective and potentially curative therapeutic modality for patients with various forms of leukemia.[1-5] In using this combined modality therapy, it is widely assumed that eradication of leukemia is primarily accomplished by high-dose chemotherapy and TBI and that the transplantation of allogeneic marrow simply acts in a supportive role to reconstitute marrow function that has been irreversibly damaged by the ablative treatment program. In addition, it has been postulated that immunologic reconstitution with allogeneic cells may in itself have a significant antileukemic effect. This view is supported by the recent finding that those transplant recipients in whom significant graft-*v*-host disease (GVHD) developed have a decreased risk of leukemia relapse compared to patients in whom GVHD does not develop.[6,7]

The present studies were undertaken to investigate the possible existence of cells with direct cytotoxicity for leukemic cells following bone marrow transplantation (BMT) and to determine whether this activity could be distinguished from GVHD. In so doing, we undertook phenotypic and functional characterization of peripheral blood lymphocytes (PBL) regenerating following allogeneic BMT in a single patient with T cell acute lymphoblastic leukemia (T-ALL) from whom we had been able to cryopreserve leukemic blasts at the time of relapse 5 months prior to transplantation. Using recently developed methods for establishing and expanding cloned cytotoxic cells without preselected specificity,[8,9] we identified four distinct clonal cell lines capable of mediating cytotoxicity against the patient's leukemic blasts. Further characterization of these cloned cell lines demonstrated that all exhibited the phenotype of natural killer (NK) cells as well as functional NK activity.

MATERIALS AND METHODS

Monoclonal antibodies. All monoclonal antibodies used in this study have been described previously. Briefly, anti-T3 defines all mature T lymphocytes.[10] T4 antigen is expressed on a subset of peripheral T cells having primarily inducer function.[11] T8 antigen is expressed on a subset of peripheral T cells having primarily cytotoxic/suppressor function.[12] Anti-T11 defines an antigen associated with the sheep erythrocyte receptor.[13] T12 antigen is expressed on a fraction of thymocytes and the vast majority of peripheral blood T cells.[13] Anti-NKH1$_A$ defines a pan-NK cell antigen that is expressed on all resting as well as activated NK cells and NK clones.[14] Anti-NKH2 characterizes a subset of large granular lymphocytes (LGL) in peripheral blood and is only expressed on some NK active clones.[14] Anti-B1 reacts with all normal B cells,[15] and anti-MY4 reacts with all peripheral blood monocytes.[16] Anti-T3, -T4, -T8, -T11, -T12, -B1, -MY4, and -NKH1$_A$ antibodies are available from Coulter Immunology, Hialeah, Fla.

Phenotypic analysis of cell surface antigens. Phenotypic analysis was performed by indirect immunofluorescence with fluorescein-

conjugated goat antimouse Fab IgG (Meloy or Tago) as previously described.[8,9] Samples were analyzed on an Epics V (Coulter Electronics, Hialeah, Fla) or a FACS 440 (Becton Dickinson, Mountain View, Calif) flow cytometer. Ten thousand cells were analyzed in each sample. Negative controls used to determine background fluorescence were ascites derived from a nonreactive hybridoma. Monoclonal antibodies were always used at saturating concentrations (1:500 to 1:1,000).

Cytotoxicity assays. Cytotoxicity assays were performed according to a standard chromium release method previously described.[8] All experiments were done in triplicate using V-bottom microtiter plates. Cytotoxicity assays were performed usually for three hours at 37 °C using 5,000 target cells/well. Medium was RPMI 1640 plus 5% pooled human AB serum and 1% penicillin-streptomycin. Target cells in these assays included Molt-4 and JM, which are T cell leukemia cell lines. K562 was derived from a patient with chronic myelogenous leukemia. U937 is a histiocytic cell line. Laz 509 is an Epstein-Barr virus (EBV)-transformed B lymphoblastoid cell line.

Preparation of lymphocyte-conditioned media. Lymphocyte-conditioned medium (LCM) was produced by stimulation of peripheral blood mononuclear cells (PBMC) at a concentration of 2×10^6 mL with 4 μg/mL phytohemagglutinin (Burroughs Wellcome, Greenville, NC), 5 μg/mL phorbol myristate acetate; (Sigma Chemical Co, St Louis), and irradiated (5,000 rad) EBV-transformed B lymphoblastoid cells (PBMC/irradiated EBV-transformed B cells ratio, 3:1). Following a first incubation for three hours at 37 °C, cells were washed four times to remove the mitogens and resuspended in RPMI 1640 supplemented with 2.5% human AB serum. After 40 hours of subsequent incubation at 37 °C, culture supernatants were harvested, passed through 0.22-μm filters and stored at −70 °C.

Generation of cloned cell lines. Methods for generation of human NK cloned cell lines have been previously described in detail.[8,9] Briefly, clones were obtained using a limiting-dilution technique at 0.5 cells/well. Cell lines were generated using the same experimental conditions, but cloning was done at 100 cells/well. Cells were cloned on a feeder layer of allogeneic irradiated PBMC (5,000 rad) plus irradiated EBV-transformed B cells (Laz 509). Initial expansion of the colonies was ensured by the addition of 10% LCM every three or four days. Culture medium was RPMI 1640 supplemented with 1% penicillin-streptomycin, 1% sodium pyruvate, and 15% human AB serum.

Cytogenetic analysis. Bone marrow cells from the patient obtained prior to transplantation were cultured for 24 hours at 37 °C. Cells were first treated with 0.1 μg/mL Colcemid (GIBCO, Grand Island, NY) for ten minutes and then with 75 mmol/L KCl for 20 minutes at 37 °C. Following hypotonic treatment, cells were centrifuged and the cell pellets broken up and fixed in 3:1 (vol/vol) methanol:acetic acid for one hour. After two changes of fixative, standard air-dried slides were prepared. Peripheral blood cultures from the donor were set up in media containing PHA, incubated for 72 hours at 37 °C, and processed as previously described. Cultured cell lines were treated with 0.01 μg/mL Colcemid for 30 minutes, treated with hypotonic KCl for ten minutes at 37 °C, and processed as previously described. All slides were stained with quinacrine mustard (25 μg/mL), rinsed in running tap water, and mounted in Tris-maliate buffer, pH 5.6. Fluorescence-banding patterns were recorded on Kodak Technicolor Pan film using a Leitz Ortholux fluorescence microscope equipped with an Orthomat camera.

CASE REPORT

This 32-year-old male was initially found to have acute lymphocytic leukemia in Dec 1980. At that time his primary complaint was chest pain and dyspnea, and chest x-ray results demonstrated a large anterior mediastinal mass. An examination of the bone marrow demonstrated a replacement of normal marrow cells with a diffuse infiltrate of lymphoblasts. Remission induction was achieved following the administration of Adriamycin, vincristine, prednisone, and L-asparaginase. He subsequently received CNS irradiation and intrathecal methotrexate and maintenance chemotherapy with intermittent cycles of prednisone, vincristine, methotrexate, and 6-mercaptopurine. Adriamycin was added to the maintenance regimen every 3 months. After 36 months of therapy, examination of the peripheral blood and bone marrow demonstrated a leukemia relapse. The peripheral WBC count was 120,000/μL, with almost all cells being lymphoblasts. The bone marrow was markedly hypercellular and was again almost totally replaced with lymphoblasts. The phenotype of bone marrow lymphoblasts as determined by indirect immunofluorescence assay and cell sorter analysis was as follows: T11+, T6−, T3 weakly +, B4−, B1−, common acute lymphoblastic leukemia antigen-negative, MY9−. Further treatment with vincristine, prednisone, Adriamycin, and L-asparaginase was able to induce a second remission.

While still in second remission, he underwent allogeneic marrow transplantation with cells from his histocompatible brother (HLA-A, -B, -C, -D identical and mixed lymphocyte culture nonreactive). Prior to infusion of marrow he received intensive therapy consisting of the following: cytosine arabinosine, 3 g/m^2 intravenously (IV) (four doses on days −5 and −4), cyclophosphamide, 60 mg/kg IV (two doses on days −5 and −4), TBI, 1,200 rad (200-rad fractions twice daily on days −3, −2, and −1). To prevent GVHD, donor marrow was treated in vitro with anti-T12 monoclonal antibody and rabbit complement to remove mature T cells.[17] The total number of cells infused was 2.2×10^9 (2.7×10^7 cells/kg). No other GVHD prophylaxis was administered. This protocol was approved by the Institutional Review Boards of the Dana-Farber Cancer Institute and Brigham and Women's Hospital. Before informed consent was obtained, the procedure and potential risks and benefits were explained to the patient and his family.

Hematopoietic reconstitution posttransplantation proceeded without complications. Nucleated RBCs were first seen in peripheral blood on day 8. Circulating granulocytes rose to levels >500/μL by day 17. The platelet count remained >20,000 without platelet transfusions after day 14. By day 19 posttransplant, the WBC count was 2,600/μL with 42% granulocytes, the hematocrit value was 37%, and the platelet count was 38,000/μL. Engraftment with allogeneic cells of donor origin was documented by cytogenetic analysis that identified chromosomal polymorphisms of donor type in metaphase preparations of marrow and stimulated peripheral blood lymphocytes posttransplantion. Acquisition of the donor-type red cell antigen phenotype was also documented posttransplant. He was discharged on day 20 after marrow transplantation. Following discharge, his clinical course was complicated by the development of right upper-quadrant abdominal pain, ascites, pedal edema, and a mildly elevated bilirubin level (total, 2.0 mg/dL). This was felt to be secondary to veno-occlusive disease of the liver and responded rapidly to treatment with oral prednisone (40 mg/d). During his early posttransplant course, mild skin erythema developed that resolved without specific treatment by day 20. Diarrhea or other manifestations of GVHD never developed. At present, he continues in remission 20 months posttransplant.

RESULTS

Phenotypic analysis of PBMC posttransplantation. At frequent intervals posttransplantation, PBMC were obtained and analyzed for reactivity with a series of monoclonal antibodies defining antigens expressed by normal T cells, B cells, NK cells, and monocytes. Results of this analysis on days 11, 18, 29, and 58 post-BMT are shown in Fig 1. In the first 3 weeks post-BMT, cells expressing NKH1$_A$ represented the major population of early reconstituting mononuclear cells. Two-color immunofluorescence assays demonstrated that the NKH1$_A$-positive cells also expressed T11/E rosette antigen but did not express T3 antigen (data not shown). Although a minor population of mature T cells expressing T3, T11, and T4 or T8 antigens were also present during this time, there were very few cells expressing T12 antigen, which is also found on normal mature T cells in peripheral blood. By 4 weeks post-BMT, the percentage of NKH1$_A$-positive cells had decreased, and the percentage of cells expressing T3, T11, and T4 or T8 antigens had increased so that T lymphocytes now represented the major population of PBMC. At this time, T cells were also found to express T12 antigen and thus displayed a more normal pattern of T cell surface markers. A high level of NK activity was maintained even after T lymphocytes became the predominant mononuclear cell in peripheral blood. When tested against K562 target cells, uncultured PBMC obtained 34 days post-BMT exhibited a 48% specific cytotoxicity at 60:1 effector/target cell (E/T) ratio, 35% at 30:1, and 22% at 15:1.

Circulating B cells identified by reactivity with anti-B1 first appeared 9 weeks post-BMT. A moderate degree of monocytosis was evident by reactivity with anti-MY4 on days 18 and 29 but did not persist after 4 weeks. During the first 3 months post-BMT, cells expressing the Ia antigen consistently represented >50% of PBMC (data not shown), suggesting that these cells were activated and proliferating in vivo. Expression of the NKH2 antigen varied between 10% and 29% of PBMC.

Generation of polyclonal lymphocytic cell lines pre- and post-allogeneic marrow transplantation. In conjunction with the phenotypic and functional characterization of lymphocyte reconstitution post-BMT, polyclonal lymphoid cell lines were established from peripheral blood obtained before and after allogeneic transplantation using in vitro stimulation and subsequent expansion with interleukin 2 (IL 2). The lymphoid cell line developed from pretransplant cells (termed TL-pre) was generated from a vial of PBMC cryopreserved at the time of leukemic relapse, 5 months prior to transplantation. Generation of this cell line was based on the assumption that a small percentage of normal T lymphocytes was still present in the peripheral blood during the acute phase of the disease. Thawed cells were stimulated with concanavalin A and cultured for 2 weeks in the presence of LCM containing IL 2. After 2 weeks, leukemic blasts were no longer detectable in the culture. Remaining viable cells were then expanded by plating 100 cells/well onto a feeder cell layer of irradiated normal PBL and EBV-transformed B cell line as described in Materials and Methods. The phenotype of this cell line is summarized in Table 1. TL-pre cells were primarily mature T lymphocytes expressing T3, T11, and T12 antigens. This cell line contained approximately equal percentages of T4+ (37%) and T8+ (32%) cells and relatively small percentages of cells expressing NKH1$_A$ (13%) and NKH2 (15%) antigens. This phenotype was clearly different from that of the T-ALL blasts, which expressed T3 antigen only weakly and did not express either T4 or T8 antigens.

Table 1. Phenotypic Analysis of Polyclonal Cell Lines Derived From Peripheral Blood Prior to and Following BMT

Cell Line	T3	T4	T8	T11	T12	NKH1$_A$	NKH2
TL-pre	86*	37	32	99	92	13	15
TL-post	66	5	73	94	33	47	35

*Percentage of cells expressing antigens defined by monoclonal antibodies.

The posttransplant cell line (termed TL-post) was established from peripheral blood obtained 83 days post-BMT and was subsequently used to develop cloned cell populations for the identification of cells with antileukemic activity. TL-post was obtained following stimulation and expansion of PBMC in LCM until sufficient numbers of cells were available for phenotypic and functional characterization. The phenotype of the TL-post cell line is summarized in Table 1. The great majority of these cells expressed T11 antigen, but in contrast to TL-pre cells, fewer cells were T3+, almost all cells were T8+, and very few were T4+. Expression of T12 antigen was less than expression of T3 antigen and was considerably weaker than in TL-pre cells. In addition, a greater percentage of the TL-post lymphocytes expressed the NK cell markers NKH1$_A$ (47%) and NKH2 (35%). More importantly, TL-post lymphocytes displayed significant activity against the patient's cryopreserved leukemic cells (23% specific cytotoxicity at 60:1 E/T ratio).

Generation of cloned cell lines displaying antileukemic activity. Cells obtained from the polyclonal TL-post cell line were cloned at 0.5 cells/well using procedures described in Materials and Methods. Clonal expansion was maintained by the addition of LCM every three days. Between 2 and 3 weeks following cloning, 74 macroscopic colonies were apparent (cloning efficiency, 30%). Cloned colonies were individually screened for cytotoxicity against uncultured freshly thawed leukemic blasts in a conventional four-hour ^{51}Cr release assay. Of the 74 colonies, six displayed cytotoxicity against the leukemic blasts. These six colonies were

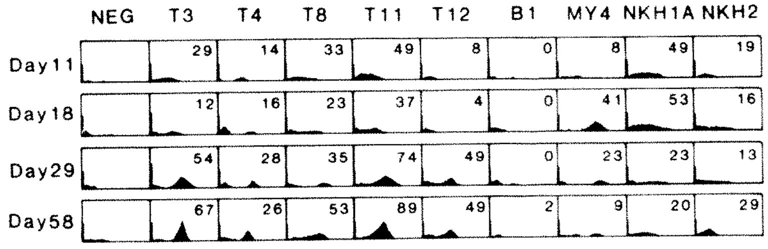

Fig 1. Phenotype of PBMC following allogeneic transplantation with anti-T12-depleted bone marrow. PBMC were analyzed on days 11, 18, 29, and 58 posttransplant. Each display represents a two-dimensional histogram plotting intensity of fluorescence on a log scale (x-axis) *v* cell number on a linear scale (y-axis) for each antibody tested. The numbers in each box represent the percentage of positive cells above the background for each reagent.

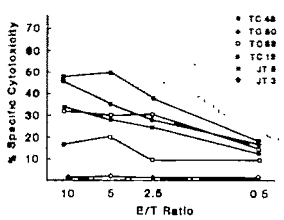

Fig 2. Cytotoxicity of clones TC12, TC48, TC50, and TC59 for leukemic T cell blasts. Effector cells (E) were incubated with target cells (T) at various ratios for three hours at 37 °C.

subcloned at 1,000 cells/well using experimental conditions identical to the initial cloning to rapidly obtain sufficient numbers of cells for further phenotypic and functional characterization. Before being discarded, all colonies that did not display cytotoxicity for the patient's leukemic cells were tested for conventional NK activity using K562 target cells. This second screening procedure identified an additional nine colonies that were strongly cytotoxic (>20% specific killing) against K562 cells but had no detectable antileukemic activity. Of the six colonies with antileukemic activity, four displayed good proliferative capacity following subcloning procedures and could be further studied in detail. These clones were termed TC12, -48, -50, and -59.

Following in vitro expansion, clones TC12, -48, -50, and -59 were retested several times against freshly thawed uncultured leukemic blasts. As shown in Fig 2, each of the four expanded clones exhibited cytotoxicity against the leukemic cells that was still evident at low E/T ratios consistent with the data obtained in the initial screening procedure. Two previously described human NK clones termed JT3 and JT9 were also used as effector cells in this representative experiment.[9] As shown, JT9 cells had a low level of cytotoxicity against the leukemic blasts, whereas JT3 cells had no activity at all. Cytocentrifuge smears of thawed target cell preparations confirmed that these target cells contained >80% leukemic blasts.

Cytotoxicity of patient clones against conventional NK target cell lines. The cytotoxic activity of the four selected clones was tested against a series of in vitro established hematopoietic cell lines that are commonly used as target cells in conventional NK assays. As shown in Table 2, the four clones were cytotoxic against K562, Molt-4, JM, and U937 cells. In contrast, there was no activity against the EBV-transformed B cell line Laz 509. These results are similar to those obtained with a series of previously described NK clones that display broad reactivity against hematopoietic cell lines but have relatively little activity against EBV-transformed B cells.[9,14]

The TC clones were also tested against normal activated T lymphocytes derived from peripheral blood cells of the patient. For this purpose, lymphocytes from the TL-pre cell line were used as target cells. It was found that TC12, -48, -50, and -59 had no cytotoxic activity against normal activated T lymphocytes autologous to the T cell leukemic blasts (Table 2).

Phenotypic analysis of clones TC12, -48, -50, and -59. Phenotypic analysis of antileukemic clones was performed using indirect immunofluorescence assays and subsequent analysis by flow cytometry. The clones were tested with a series of monoclonal antibodies that have been previously used to characterize NK cloned cell lines derived from normal donors and are included for comparison in Table 3. TC48 cells were found to express $NKH1_A$ antigen but did not react with anti-T3, -T4, -T8 or -T11. This pattern of reactivity appeared to be similar to that of a previously described clone termed JT1.[8,14] However, as opposed to JT1 cells, TC48 cells did not express NKH2 antigen. It was also found that TC48 cells did not react with anti-$T11_2$ and anti-$T11_3$ antibodies, which define other epitopes of the E rosette receptor molecule[18] (data not shown). Clone TC59 was found to express T11 as well as $NKH1_A$ and NKH2 antigens, a phenotype similar to that of the cloned NK cell line JT3.[14] Clones TC12 and TC50 displayed an identical phenotype using this series of antibodies. These two latter clones were found to express T11 and $NKH1_A$ but did not react with anti-NKH2 and were thus similar to the NK clone JT_B18.[14] None of the clones expressed the T cell antigens T3, T4, or T8.

Cytogenetic characterization of clones TC12, -48, -50, and -59. Quinacrine bright polymorphisms were compared between metaphases obtained from the patient's bone marrow cultures and PHA-stimulated leukocyte cultures from the donor. One informative polymorphism was observed. Although both copies of chromosome 21 from the patient lacked any polymorphism (Fig 3A), one of the copies of chromosome 21 in the donor had quinacrine bright satellites (Fig 3B). Twenty-seven Q-banded metaphases from the four clones were analyzed. All of them had a chromosome 21 with the bright satellites (Fig 3C), indicating that the clones are derived from donor cells.

DISCUSSION

In the present study, peripheral blood cells from a single individual were analyzed at various times during immunologic reconstitution following allogeneic BMT with T cell–depleted marrow. The primary goal of this characterization was to identify those cells that might be capable of exerting a

direct cytotoxic effect against the patient's leukemic blasts. In this regard, we found that the major population of PBMC reconstituting during the first 3 weeks post-BMT had an NK cell phenotype and exhibited high levels of NK activity. Only after 1 month did large numbers of T cells develop. At 12 weeks post-BMT, the peripheral blood still contained 24% $NKH1_A$-positive cells, and a polyclonal cell line established at this time was able to mediate a relatively low but significant level of cytotoxic activity against freshly thawed leukemic cells that had been cryopreserved at the time of relapse. To identify the cells responsible for this antileukemic activity, cultured cells were cloned at 0.5 cells/well using techniques that had previously been developed to establish clonal populations of NK-active cells from normal individuals. Using these techniques, four different clonal cell lines with antileukemic activity could be identified and propa-

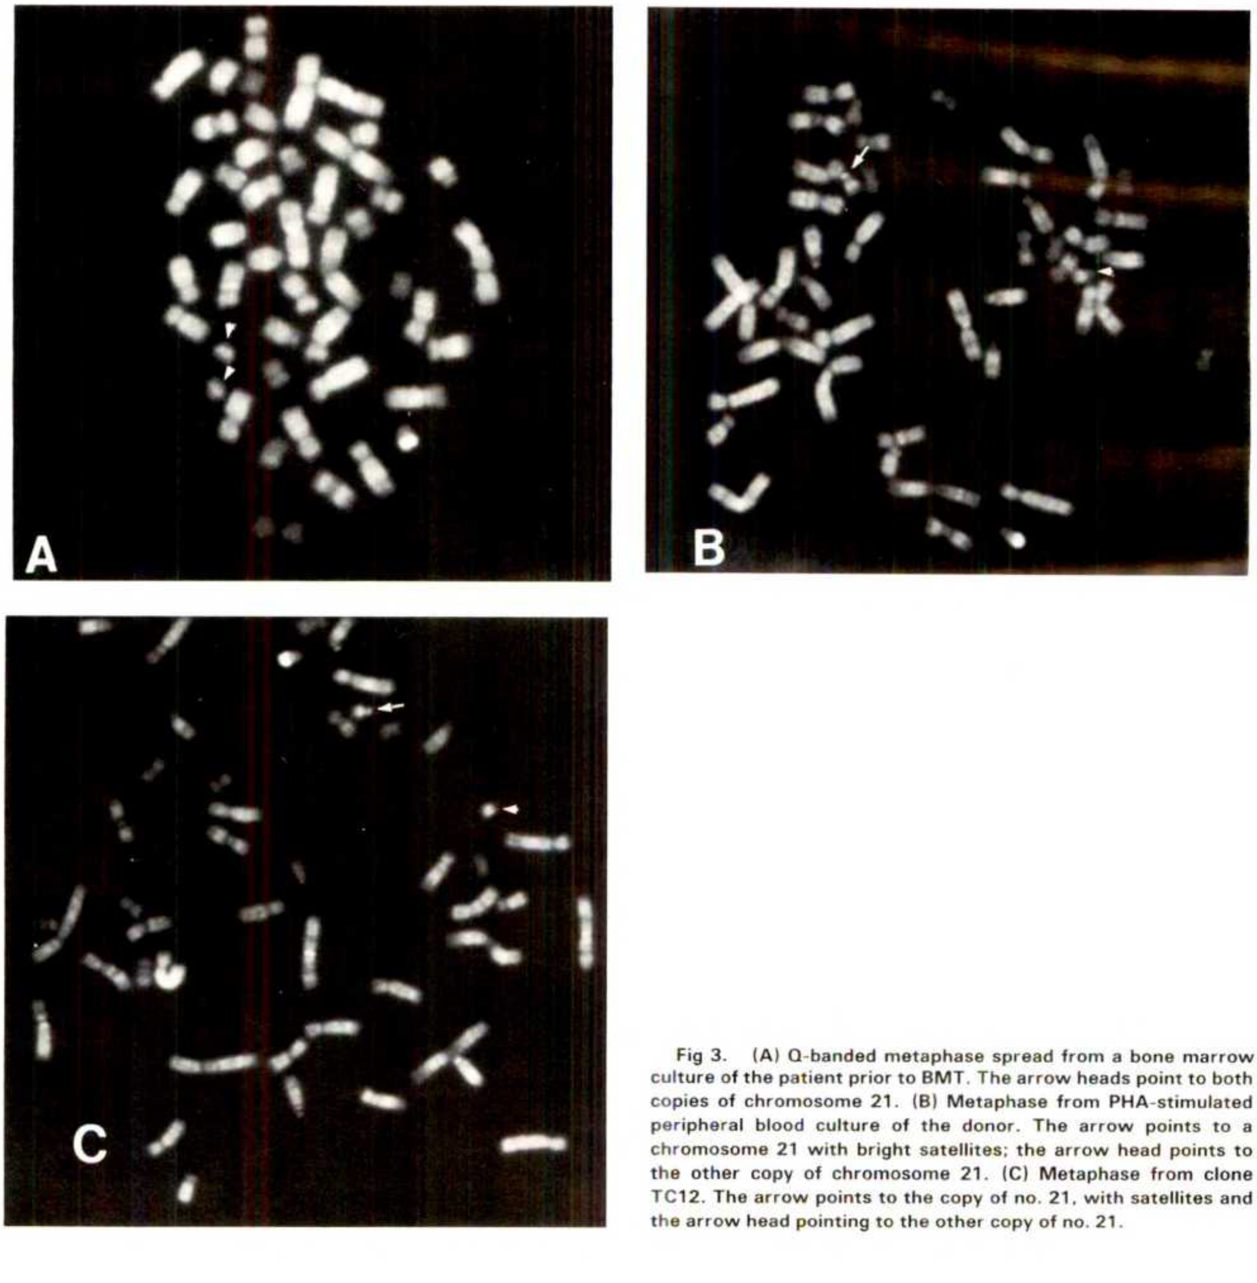

Fig 3. (A) Q-banded metaphase spread from a bone marrow culture of the patient prior to BMT. The arrow heads point to both copies of chromosome 21. (B) Metaphase from PHA-stimulated peripheral blood culture of the donor. The arrow points to a chromosome 21 with bright satellites; the arrow head points to the other copy of chromosome 21. (C) Metaphase from clone TC12. The arrow points to the copy of no. 21, with satellites and the arrow head pointing to the other copy of no. 21.

gated in sufficient numbers to allow a detailed phenotypic and functional characterization. Cytogenetic analysis confirmed that each clone was derived from the HLA-compatible allogeneic donor. Immunofluorescence analysis of cell surface markers demonstrated that each clone had a characteristic phenotype representative of NK cells and that these phenotypes were similar to those of NK clones previously derived from normal individuals. Finally, each clone was cytotoxic for standard NK target cells as well as for leukemic blasts, but these clones did not exhibit cytotoxicity for normal activated T cells derived from the patient prior to BMT.

Taken together, the clonal analysis of cytotoxic cells in our patient suggests that activated NK cells derived from the donor may be capable of exerting a direct antileukemic effect following allogeneic marrow transplantation. This conclusion is consistent with the results of experiments in animal models that have suggested that NK cells play a role in normal immune resistance to radiation-induced leukemias as well as other hematopoietic and nonhematopoietic tumors.[19] In the context of marrow transplantation, however, NK cells have been implicated in a number of sometimes conflicting responses. For example, several studies have demonstrated that NK cells in the host can mediate immunologic resistance to an allogeneic marrow graft.[19-21] It has also been suggested that NK cells in the allogeneic graft play a role in producing GVHD,[22-24] whereas other studies have found no correlation between NK activity post-BMT and either leukemia relapse or GVHD.[25] The implication of NK cells in such diverse activities may reflect the extensive phenotypic and functional heterogeneity of these cells. In previous studies, we and others have established cloned cell lines that maintain NK activity from normal peripheral blood and have used these cultured cells to characterize NK activity at the single-cell level.[9,19,26,27] The diversity of phenotypes and functional specificity demonstrated with these cloned NK cell lines appeared to reflect the heterogeneity of uncultured cells capable of mediating NK function, and several of these cloned cell lines were used for comparative purposes in the present analysis. Of interest, several normal NK clones were either not able to kill our patient's cryopreserved leukemic cells or had very low levels of activity even though their phenotype and cytotoxicity for other NK targets was similar to that seen with clones TC12, -48, -50, and -59. Moreover, it should also be pointed out that the ability to kill leukemic targets was not shared by all NK-active clones established post-BMT. In fact, only six of 15 clones having a high degree of cytotoxicity for K562 were able to kill leukemic targets, again demonstrating the extensive heterogeneity of cells capable of mediating NK-like functions.

In part, our clonal analysis of cytotoxic cells post-BMT was facilitated by the method we used to prevent GVHD. More specifically, this patient received allogeneic marrow that was depleted of mature T cells by in vitro treatment with anti-T12 antibody and rabbit complement.[17] He did not receive any other GVHD prophylaxis. T12 antigen is normally expressed on functionally mature T lymphocytes in peripheral blood and thymus but is not expressed on less-differentiated T cells within the thymus and, more importantly, is not expressed to any large extent on normal NK cells. The early proliferation of NK cells and delayed proliferation of mature T cells in our patient therefore likely reflects the in vitro treatment with anti-T12, which is more effective in depleting T cells than NK cells. NK cells normally reconstitute in the early posttransplant period and have been associated with acute GVHD, but NK cell proliferation would occur in the context of rapid T cell proliferation if T cells were not depleted from the donor marrow prior to transplantation.[28] The finding that NK cells can reconstitute in large numbers without the development of clinically significant GVHD suggests that these cells are not responsible for GVHD. The additional finding that cloned NK cells from the donor are capable of cytotoxicity against the recipient's leukemic cells further suggests that it may be possible to distinguish graft-*v*-leukemia from GVHD following human marrow transplantation as has previously been demonstrated in murine experiments.[29]

Although the present studies suggest that donor NK cells may play a role in preventing leukemia relapse after marrow transplantation, it should be emphasized that our studies were carried out in a single patient with T-ALL. We have not yet analyzed NK cells in other allogeneic transplant recipients with different types of leukemia or following autologous or syngeneic transplantation. The clonal analysis of cytotoxic effector cells is a laborious method that cannot easily be applied to large numbers of patients, but similar studies will have to be carried out in additional patients before the clinical significance of NK cells post-BMT is fully understood.

ACKNOWLEDGMENT

We would like to thank Dr Jose Noy and Dr Robert Mayer for referring this patient; Herbert Levine and John Daley for assistance with flow cytometric analysis; and Felice Coral, RN, and the nurses and staff of the Brigham and Women's Hospital Bone Marrow Transplant unit for their diligent care.

Acid Phosphatase Activity in Mononuclear Phagocytes and the U937 Cell Line: Monocyte-Derived Macrophages Express Tartrate-Resistant Acid Phosphatase

By Rose G. Snipes, K.-W. Lam, Richard C. Dodd, T. Kenney Gray, and Myron S. Cohen

Tartrate-resistant acid phosphatase (TRAcP) is used as a marker for osteoclasts, which are believed to be derived from phagocytic cells or phagocyte stem cell precursors. To further investigate the relationship between monocytic phagocytes and osteoclasts, acid phosphatase (AcP) activity was measured by three different techniques in human peripheral blood monocytes, monocyte-derived macrophages, and the U937 cell line. We found that cytochemistry and gel electrophoresis led to similar results, but that the colorimetric assay was inconsistent. Normal human peripheral monocytes expressed both tartrate-sensitive and -resistant AcP. In culture these cells formed polykaryons and expressed TRAcP activity that was further identified as an isoenzyme associated with bone tissue. In contrast, the U937 cells did not express TRAcP activity as measured by gel electrophoresis. Both U937 cells and monocytes possess material that interferes with interpretation of the colorimetric assay of AcP. The presence of TRAcP in monocyte-derived macrophages further supports the relationship between phagocytic cells and bone osteoclasts.

ACID phosphatases (AcP)[1] are enzymes found in all body tissues including human leukocytes.[1-3] These enzymes hydrolyze monophosphate esters in an acid environment. AcP activity can be demonstrated in individual cells by histochemical techniques[4,5] or in extracted tissue by either colorimetric reactions[1] or acrylamide gel electrophoresis.[6,7] These enzymes are divided into two major groups based on their sensitivity to tartrate inhibition. Most of the AcP in normal serum is tartrate resistant.[8] Tartrate-resistant acid phosphatase (TRAcP) is associated with bone tissue,[9-11] the neoplastic cells of leukemic reticuloendotheleosis (hairy-cell leukemia[12-14]), and spleen cells from patients with Gaucher's disease.[14-16] TRAcP activity has been identified by cytochemical stain in multinucleated giant cells of bone (osteoclasts), and this enzyme is regularly used as a marker for osteoclasts.[10,17]

The mechanisms by which monocytic phagocytes (or their precursors) differentiate into osteoclasts remain unknown. Furthermore, because of the difficulty in obtaining sufficient monocytes for study as well as their maturity after release from the bone marrow, we and others have used a variety of cell lines for studies of monocyte differentiation.[7,18-20] U937, a cell derived from a histiocytic lymphoma,[21] will differentiate into a macrophagelike cell[7,18,20] and form multinucleated giant cells (polykaryons) under appropriate conditions of incubation. Because of the significance of TRAcP activity to the operational definition of the osteoclast,[10,17] we conducted detailed studies of the AcP chemistry of human peripheral blood monocytes, monocyte-derived macrophages, and the U937 cell line. Our results demonstrate major differences between human monocytes and the U937 cell line. Furthermore, we have identified the TRAcP isoenzyme associated with bone tissue and osteoclasts in monocyte-derived macrophages.

MATERIALS AND METHODS

Reagents

1,25-dihydroxyvitamin D_3 ($1{,}25(OH)_2D_3$) was obtained as a gift from Milan Uskokovic, PhD, Hoffmann-LaRoche, Nutley, NJ. The $1{,}25(OH)_2D_3$ was dissolved in 100% ethanol and added to cell cultures to give a final ethanol concentration of 0.1%. In all experiments, appropriate controls were performed to exclude an ethanol effect.

Isolation and Preparation of Cells

Human monocytes. Venous blood was obtained from normal volunteers consistent with the guidelines of the Human Rights Committee of the University of North Carolina at Chapel Hill. Human monocytes were prepared as previously described[22] by placing heparinized whole blood on a Plasmagel (Cellular Products, Buffalo) sedimentation gradient. The white cell layer was removed, centrifuged, and the pellet diluted in phosphate-buffered saline and placed on a Ficoll-Hypaque gradient (specific gravity 1.077, Sigma Chemical Co, St Louis, and Winthrop Laboratories, New York). Cells were centrifuged at 150 g for 35 minutes. The mononuclear layer was removed, centrifuged at 200 g for 10 minutes, and subsequently washed three times in alpha-modified minimal essential medium (alpha MEM, GIBCO, Grand Island, NY). Cells were enumerated in a Coulter Counter (Coulter Electronics, Hialeah, Fla). As judged by nonspecific esterase staining, greater than 90% of the cells were monocytes. The cells were plated in 35 × 100-mm Falcon 3001 plastic Petri dishes (Falcon Labware, Oakland, Calif) at a density of 3.5×10^6 monocytes/mL. Cell viability was >90% as determined by trypan blue exclusion. Cell culture media consisted of alpha MEM supplemented with 10% autologous human serum, 15 mmol/L HEPES, 2 mmol/L L-glutamine, penicillin (100 U/mL), and streptomycin (100 μg/mL). After two hours of incubation at 37 °C in humidified 5% CO_2, the nonadherent cells and overlying media were removed and the plates washed three times with Hanks' balanced salt solution (HBSS). Fresh media containing variables to be examined were then added to the monolayer, and cells were incubated at 37 °C for three to seven days. Media were changed after three days of incubation.

U937 cells. U937 cells obtained from the tissue culture facility of the Lineberger Cancer Research Center (UNC-CH) were plated at 2×10^6 cells/mL in Dulbecco's modified MEM/Ham's F-12

medium (GIBCO) that was supplemented with 5% fetal bovine serum, penicillin (100 U/mL) and streptomycin (100 μg/mL).

Acid Phosphatase Determinations

Cytochemistry. Human monocytes were isolated as previously described, placed on tissue culture slides (LAB-TEK, Miles Scientific, Naperville, Ill), and incubated for the desired length of time. At the end of the incubation the media were removed. The slides were washed and air dried. U937 cells were suspended in culture media as previously described. At the end of the desired incubation period, cytopreparations were made of the cell suspensions by centrifugation at 1,500 rpm for five minutes (Shandon-Elliott Cytospin, Sewickley, Pa). Cytopreparations of U937 cells and adherent monocytes were air dried, fixed, and stained as described by Janckila et al.[4]

Colorimetric determination. Human monocytes were incubated the desired length of time, and the culture media were removed. Plates were washed twice with HBSS. The adherent monolayer was then disrupted with a rubber policeman in a 1-mL vol of 10 mmol/L N-tris[Hydroxymethyl]methyl 2-aminoethanesulfonic acid (TES) buffer. Cells disrupted by sonication and suspended in buffer were used in the biochemical assay. U937 cells were cultured for the desired period of time and washed three times in HBSS. The cell pellet was diluted to a concentration of 5×10^6 cells/mL in 10 mmol/L TES (pH 7.4). This suspension was sonicated for 30 seconds to form an extract. The extract was then centrifuged at 150 g for ten minutes. The supernatant was removed and used in the biochemical analysis. U937 cells treated with $1,25(OH)_2D_3$ required removal with a rubber policeman. The cells were then counted and prepared as described for the immature U937 cells.

Cell extracts (0.1 mL) were mixed with an assay mixture containing 9.2 mmol/L para-nitrophenylphosphate (P-NPP, Sigma) and 0.1 mol/L acetate buffer (pH 6) in a final volume of 0.60 mL. For the determination of TRAcP, the reaction mixture included 10 mmol/L L-sodium tartrate (Mallinkrodt, Inc). The reaction was stopped by the addition of 2.5 mL 0.05 mol/L NaOH. The color was measured at 410 nm in a Beckman Acta V spectrophotometer (Beckman Instruments, Inc, Fullerton, Calif). A Lowry protein assay was run simultaneously on cell extracts.[23] The amount of hydrolyzed P-NPP was then calculated by comparing the absorbance of the sample to a standard solution of P-NPP. Enzyme activity is defined as nanomoles of substrate hydrolyzed per minute (milliunits). L-ascorbic acid (10^{-3} mol/L) and Fe^{+2} (10^{-4} mol/L) were also added to some of the cell extracts containing L-sodium tartrate.

Isoenzymes determination. Human mononuclear phagocytes and U937 cells were cultured for the desired period of time. Media from phagocytes and U937 cells were removed and culture dishes washed vigorously with HBSS to remove residual serum. Cell extracts were analyzed by electrophoresis on an acidic acrylamide gel as previously described by Lam et al.[6]

RESULTS

Histochemistry of AcP Activity

Monocytes isolated from the peripheral blood of normal human volunteers were separated from lymphocytes by two

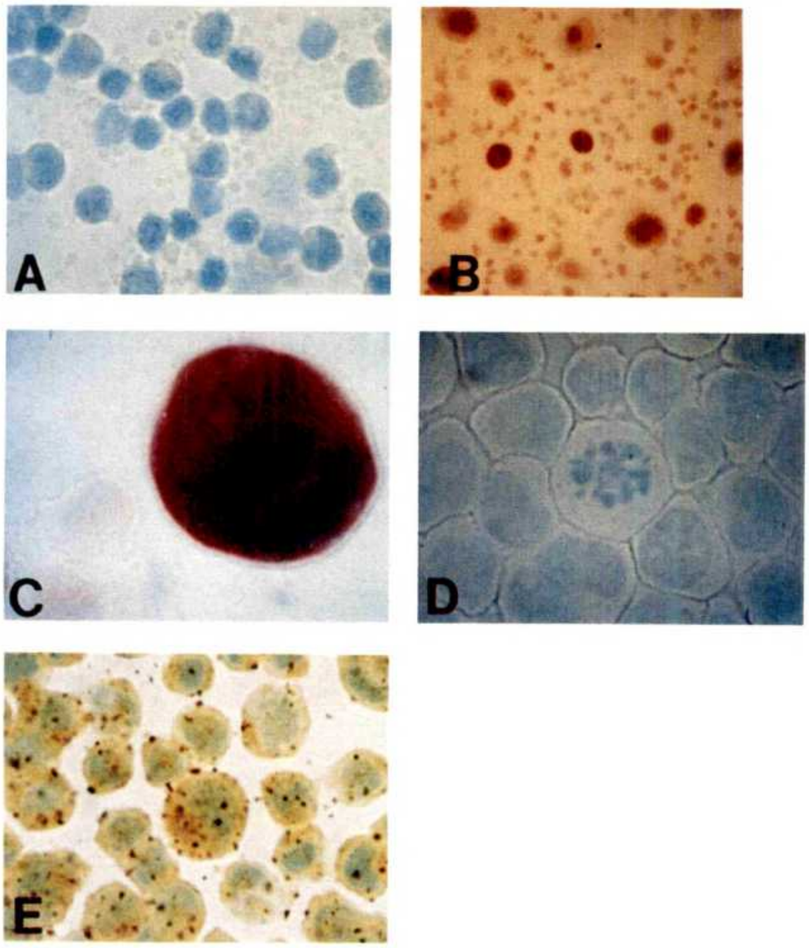

Fig 1. Light microscopic examination of phagocytic cells. TRAcP activity is represented by red stain. (A) Peripheral blood monocytes at two hours of culture have no tartrate-resistant activity (original magnification × 10). (B) After three days of culture, human monocytes demonstrate TRAcP activity. The activity is most intense in multinucleated giant cells (original magnification × 10). (C) Close-up of three-day giant cell with strong TRAcP activity (original magnification × 100). (D) Replicating U937 cells demonstrate no TRAcP activity (original magnification × 40). (E) In the presence of $1,25(OH)_2D_3$, a speckled pattern is seen that appears to represent extracellular enzyme activity (original magnification × 40).

hours of adherence and examined using standard staining technique for total and TRAcP activity.[4] As shown in Fig 1A, AcP expressed by these cells was inhibited by Na tartrate. After three days of incubation, monocytes developed the appearance of monocyte-derived macrophages,[22,24] and an increased number of multinucleated giant cells was noted. All cells demonstrated TRAcP activity, which was most intense in multinucleated giant cells (Fig 1B and C). Cells cultured over a seven-day period continued to express this activity.

We and others[18,19,25,26] have recently demonstrated a variety of effects of $1,25(\mathrm{OH})_2\mathrm{D}_3$ on the U937 cell line. This cell line also resorbs devitalized bone chips in vitro.[7] We examined the cytochemical AcP activity of this cell line under conditions similar to normal monocytes. Replicating (immature) U937 cells demonstrated tartrate-sensitive AcP activity (Fig 1D). Cells incubated for three days with $1,25(\mathrm{OH})_2\mathrm{D}_3$ (10^{-8} mol/L) showed increased maturation, as has been previously reported.[18,19] However, tartrate-sensitive AcP activity continued to be the primary enzyme expressed. A few cells demonstrated TRAcP activity in a speckled pattern near the cell membrane (Fig 1E).

Colorimetric Analysis

AcPs hydrolyze *p*-nitrophenol phosphate rapidly at a pH of 5 to 5.5. Peripheral blood monocytes demonstrated both tartrate-sensitive and tartrate-resistant AcP activity (Table 1). Monocytes in culture for three to seven days developed an increase in this activity (Table 1). Most of the activity was resistant to tartrate. Immature U937 cells demonstrated less AcP than human monocytes. U937 cells were differentiated by exposure to $1,25(\mathrm{OH})_2\mathrm{D}_3$, but only small differences were noted in AcP expression (Table 1). These results conflicted with the cytochemical examination and prompted further analysis of this enzyme activity.

Isoenzyme Expression of AcP

AcPs isolated from human tissues migrate as five distinct bands on gel electrophoresis, and these bands most likely represent distinct isoenzymes.[6,27] TRAcP can be localized to band 5, which migrates farthest toward the cathode. Band 5 appears as two components designated as 5a and 5b. They differ only by a carbohydrate moiety present on 5a, which can be removed by sialidase.[1] Band 5b can also be isolated from osteoclasts,[28] the neoplastic cells of leukemic reticuloendotheliosis,[13,14] and phagocytes of Gaucher's disease.[15-17] Freshly isolated monocytes studied by gel electrophoresis demonstrated only band 4 (tartrate-sensitive) activity, as previously reported (Fig 2).[22] Monocyte-derived macrophages cultured for three to seven days expressed band 5b (Fig 3). Monocytes incubated with $1,25(\mathrm{OH})_2\mathrm{D}_3$ also demonstrated band 5b on gel electrophoresis (data not shown).

Table 1. AcP Expression by Phagocytic Cells (mU P-NPP Hydrolyzed/mg Protein)

	AcP	TRAcP	Percentage of TRAcP
U937 cells (replicating)	9.6 ± .34	8.3 ± .3	86
U937 cells (differentiated)*	13.7 ± .36	10.6 ± .22	77
Monocytes	16.7 ± 5.9	13.9 ± 6.6	83
Monocyte-derived macrophages (three days in culture)	36.2 ± 3.8	25.3 ± 2.4	70

*Phagocytes were cultured for three days in the presence of 10^{-8} mol/L $1,25(\mathrm{OH})_2\mathrm{D}_3$.

Results are the mean ± SD of three to four separate experiments, each performed in duplicate.

In the U937 cell, only band 4 was detected, whether the cells were replicating or not. Band 4 activity was greater in the U937 cells incubated with $1,25(\mathrm{OH})_2\mathrm{D}_3$. Band 5b was not observed under these conditions (Fig 4). These results supported our cytochemical observations (Fig 1). To further evaluate the AcP activity of U937 cells, a cellular extract was eluted over a diethylaminoethyl (DEAE) cellulose column (Fig 5). Over 90% of the AcP activity eluted as a single peak that was tartrate sensitive and migrated on gel electrophoresis as band 4. Band 5b was not observed in this cell extract even after the addition of ferrous iron and ascorbic acid. These compounds are known to enhance the expression of the TRAcP.[29] The substance(s) responsible for the TRAcP activity observed in the colorimetric assay of the crude U937 extract and freshly isolated human monocytes has not been as yet identified.

DISCUSSION

TRAcP can be isolated in high concentration from bone.[9,28,29] Although the cell of origin of this enzyme has not

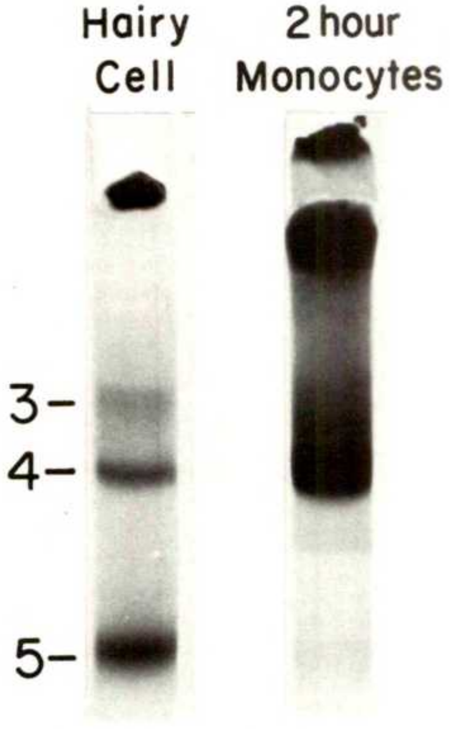

Fig 2. Gel electrophoresis of freshly isolated peripheral blood monocytes. Only band 4 activity is seen.

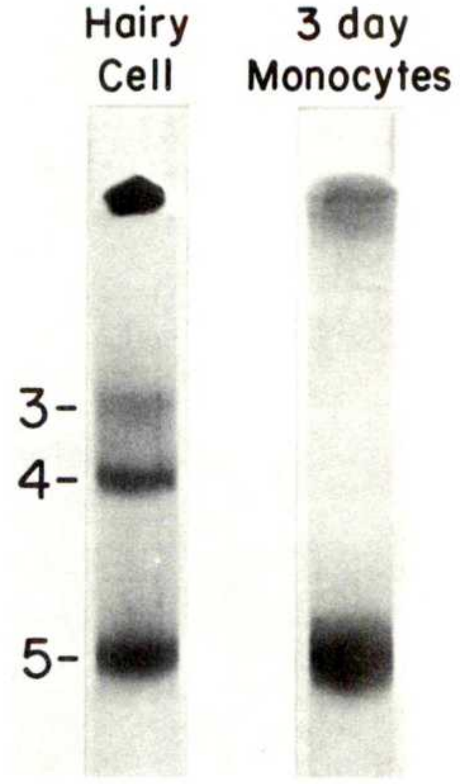

Fig 3. Gel electrophoresis of monocyte-derived macrophages (three days) in which band 5b activity is seen.

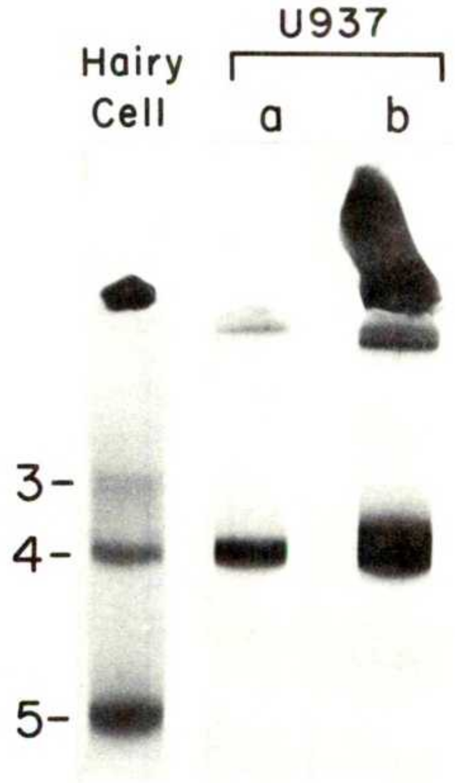

Fig 4. Gel electrophoresis of U937 cells: (A) Replicating cells have only band 4 activity. (B) In the presence of $1,25(OH)_2D_3$ band 4 activity is enhanced. Band 5 activity cannot be demonstrated.

been clearly defined, morphologic evidence suggests that TRAcP is associated with the osteoclast.[17] TRAcP is routinely used to identify osteoclasts isolated from bone or osteoclastlike cells in culture.[1,5,10] Several lines of evidence suggest that osteoclasts are derived from mononuclear phagocytes, although it is unclear whether peripheral blood monocytes[30,31] or stem cells[32,33] are required for such differentiation. In the present study we evaluated the AcP activity of peripheral blood monocytes, monocyte-derived macrophages, and the U937 cell line, a model for monocytic phagocytes.[21] Our methods included cytochemistry, colorimetric analysis, and gel electrophoresis. Cytochemical and colorimetric assays are widely used, and can be confirmed by gel electrophoresis[1,6] or immunoassay.[34]

Cytochemical analysis revealed only minimal TRAcP activity in freshly isolated normal human peripheral blood monocytes, a finding consistent with previous reports.[3,27,35] The strong TRAcP in cultured monocytes is consistent with recent observations by Weinberg and colleagues who demonstrated TRAcP activity in polykaryons formed from peripheral blood monocytes cultured in the presence of interferon-γ.[36]

U937 cells replicate in culture, remain in suspension, and are immature monocytes by several criteria.[21] These cells expressed only tartrate-sensitive cytochemical AcP activity. Cells incubated in the presence of $1,25(OH)_2D_3$, a known inducer of differentiation, occasionally expressed a speckled pattern of TRAcP activity. This pattern appeared to be located at the plasma membrane and may represent the absorption of the enzyme from serum in the culture medium.[8]

A colorimetric assay demonstrated TRAcP activity in both monocytes and U937 cells. This finding differed from the results derived from the cytochemical assay. To resolve this discrepancy, extracts from monocytes and U937 cells were evaluated by gel electrophoresis. Only band 4 of the

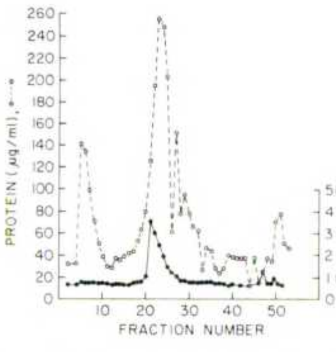

Fig 5. The U937 cell was subjected to sonication for one minute then centrifuged for 15 minutes at 20,000 g. The insoluble particulate fraction was discarded. The soluble proteins in the supernatant fraction were transferred to a DEAE-cellulose column (0.9 × 30 cm), and eluted by a linear concentration gradient of NaCl–10 mmol/L Tris-sulfate, pH 8. The eluate was analyzed for protein concentration and AcP activity by the colorimetric method. Most of the AcP activity was recovered in one peak corresponding to band 4 as detected by the electrophoresis method.

AcP isoenzymes was observed in the freshly isolated monocytes. Monocyte-derived macrophages expressed band 5b. The U937 cells showed only band 4, which increased after exposure to $1,25(OH)_2D_3$ Anderson and Toverud have previously reported that iron and ascorbic acid enhanced detection of TRAcP activity.[29] No band 5b was seen in the U937 cells, even in the presence of ferrous iron and ascorbic acid Ninety percent of the total AcP activity in the U937 cells was isolated chromatographically and identified as band 4.

These results have several important implications for the study of AcP. It seems clear that the various assays available for the detection of acid phosphatase do not uniformly agree. In our hands the cytochemical assay correlated best with the results of gel electrophoresis. Although the latter technique is relatively cumbersome, the results are more specific than for the colorimetric assays frequently used Phagocytic cells appear to possess substance(s) that interfere with use of the colorimetric identification of TRAcP.

Isoenzyme 5b was not observed in the U937 cell line even though it is an established monocytic cell model. Band 5b, an isoenzyme characteristic of osteoclasts,[28] was expressed in monocyte-derived macrophages. These findings demonstrate a biochemical link between the monocyte-derived macrophages and osteoclasts.

Hydroxyurea Induction of Hemoglobin F Production in Sickle Cell Disease: Relationship Between Cytotoxicity and F Cell Production

By G.J. Dover, R.K Humphries, J.G. Moore, T.J. Ley, N.S. Young, S. Charache, and A.W. Nienhuis

Initial alterations in fetal hemoglobin (HbF) production among eight sickle cell anemia subjects treated with hydroxyurea (Hu) are summarized. Four of these subjects had been previously treated with 5-azacytidine (5-aza). All subjects treated with Hu (50 mg/kg/d for three to five days) had suppression of their total reticulocyte counts by seven days, whereas the four subjects previously treated with 5-aza (2 mg/kg/d for three to five days) had increased reticulocyte counts at day 7. The effect of Hu on increasing the number of HbF-containing reticulocytes (F reticulocytes) is extremely variable, ranging from ten- to less than onefold differences in maximal posttherapy *v* pretherapy levels. Recovery from marrow suppression did not result in greater than twofold increases in F reticulocyte counts. Mean day 7 F reticulocyte levels in the four subjects treated with both Hu and 5-aza were 4.1 × 10/μL and 15.4 × 10^4/μL, respectively.

Among Hu-treated subjects, increased F reticulocyte production was correlated with low serum creatinine levels and rapid removal of Hu from the plasma. Furthermore, suppression of CFU-E colony formation on day 2 of therapy with Hu was inversely correlated with maximal F reticulocyte response. We conclude that where Hu treatment results in marrow toxicity (decreased reticulocyte counts, decreased CFU-E colony formation) HbF production is less likely to increase. Those sickle cell anemia subjects with minimal renal dysfunction (serum creatinine level, >1.0 mg/dL) exhibit the most cytotoxicity and least F reticulocyte response to Hu.

© 1986 by Grune & Stratton, Inc.

INCREASED fetal hemoglobin (HbF) production may potentially decrease the clinical severity of sickle cell (SS) anemia.[1] Recently it was shown that 5-azacytidine (5-aza)[2-4] and hydroxyurea (Hu)[5] could increase HbF production in SS disease. The mechanisms by which these two agents increase HbF is unclear. Several investigations have suggested that these agents kill late erythroid precursors (CFU-E), leading to recruitment from earlier progenitors (BFU-E) that have retained their HbF-producing capacity.[6-8] In previous reports we have demonstrated that 5-aza rapidly increases HbF production without marrow toxicity[9] and without reduction in CFU-E colony formation.[10]

In this report we summarize initial responses to Hu therapy in four SS subjects who previously responded to 5-aza and report observations on four additional subjects who have been given Hu only. Unlike 5-aza therapy, which causes little if any toxicity in the first seven days of therapy, Hu therapy leads to early suppression of the reticulocyte count and in some patients to decreased CFU-E colony growth. Marked variation in the ability to increase HbF production was seen in the Hu-treated patients. Increased HbF production was observed only in those patients with rapid decrease of Hu from their plasma and with the least suppression in CFU-E and BFU-E colony formation.

MATERIALS AND METHODS

Subject selection All subjects studied were adults with SS disease followed at Johns Hopkins Hospital (subjects A, C, and E) or the National Institutes of Health (NIH) (subjects 6, 7, 10, 11, and 12). The effects of an optimal dose of 5-aza (1.5 to 2 mg/kg/d) on subjects A, C, 6, and 7 have been previously reported [4,9,10] Subjects E, 10, 11, and 12 were given only Hu. The dose of Hu, 50 mg/kg/d for three or five days, was chosen on the basis of previous reports in animals and man.[5,6] Subjects 6 and 7 were given an additional single dose of Hu (25 mg/kg) and followed for seven days All subjects gave informed consent for these experiments under the guidelines outlined by the Joint Committee on Clinical Investigation at Johns Hopkins Hospital or the National Heart, Lung, and Blood Institute Review Board

HbF production Previously described radial immunoprecipitation assays were used to estimate the percentage of HbF-containing reticulocytes (F reticulocytes).[11] The red cell number was enumerated in a Coulter Counter (Coulter, Hialeah, Fla), and the percentage of total reticulocytes was estimated after staining with new methylene blue.

Hu levels. Plasma Hu levels were analyzed by the method of Fabricius and Rajewsky.[12] The assay is a colorimetric procedure based on the oxidation of Hu, with iodine forming nitrite that diazotizes sulfanilic acid. The diazotized sulfanilic acid is then coupled with *N*-(1-napthyl)-ethylenediamine dihydrochloride to produce a red color Samples were separated from whole blood, frozen at −20 °C and assayed within two days of collection. Serum creatinine levels were determined at least five times prior to and during experimental therapy by routine clinical methods

In vitro analysis Assays of early and late erythroid progenitors (BFU-E and CFU-E) were performed as previously described[10] in cultures that contained 0.8% methylcellulose (Dow Chemical Co, Midland Mich), 30% fetal calf serum (Flow Laboratories, McLean, Va), 2.5 μ/mL of erythropoietin (Connaught Laboratories, Willowdale, Canada), and 10% phytohemagglutinin-stimulated leukocyte-conditioned media.

RESULTS

F reticulocyte response. Figure 1 details the F reticulocyte response of eight SS subjects given Hu A greater than twofold increase in the F reticulocyte occurred in only four subjects (10, 12, A, E). Figure 2A illustrates that all eight subjects showed a decrease in total reticulocytes after seven days of Hu therapy. In contrast, the four subjects previously

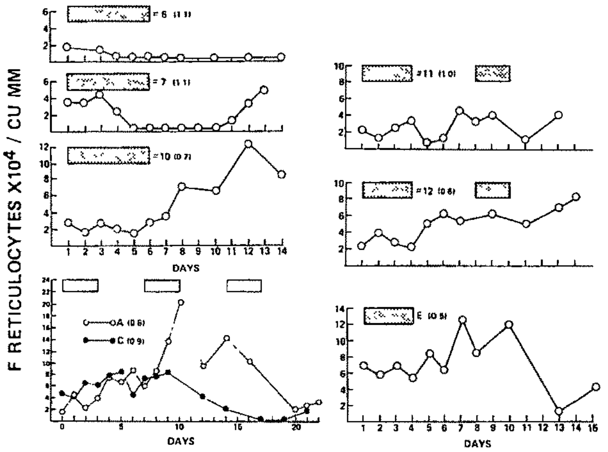

Fig 1. F reticulocyte response to Hu therapy. Each subject was treated with 50 mg/kg/d (shaded boxes). The number in parentheses refers to the serum creatinine level of each subject.

treated with 5-aza (A, C, 6, 7) showed no evidence of reticulocyte suppression at seven days following 5-aza therapy. Reticulocyte levels returned to pretreatment levels within seven days of their nadir in all Hu-treated subjects except subject 6. Subject 6 required a transfusion on day 15, after the hemoglobin level dropped from 9.8 to 5.0 g/dL following Hu administration. F reticulocyte levels increased with recovery from marrow suppression in subject 7, but the maximal F reticulocyte response (day 13) was not greater than twofold the pretreatment levels.

In all eight subjects given Hu, day 7 F reticulocyte levels were lower than those attained in the four subjects given 5-aza (Fig 2B). The mean day 7 F reticulocyte level for the four subjects given 5-aza and Hu were 15.4 × $10^4/\mu L$ and 4.1 × $10^4/\mu L$, respectively

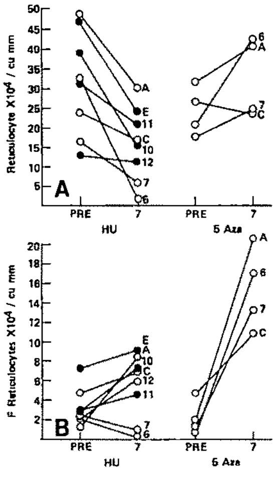

Fig 2. Comparison of the effect of Hu and 5-aza on (A) the total reticulocyte count and (B) the F reticulocyte count. Pretherapy (PRE) and day 7 (7) values are given. Open circles indicate subjects treated with both drugs. Closed circles are subjects treated only with Hu. Numbers and letters are the same as listed in Fig 1.

The two subjects who exhibited the most toxicity (6 and 7) were given a lower dose of Hu (25 mg/kg) and followed for seven days. In subject 6 the total reticulocyte count decreased slightly (41 to 34 × $10^4/\mu L$), and the F reticulocyte count did not change (1.5 to 1.6 × $10^4/\mu L$). Subject 7's total reticulocyte count also decreased (32 to 24 × $10^4/\mu L$), but his F reticulocyte count increased (3.8 to 7.0 × $10^4/\mu L$).

Hu levels. Normally more than 80% of Hu is excreted within six hours in the urine.[13,14] Plasma Hu levels were measured following a standard oral dose of 25 mg/kg of Hu in all eight subjects. Plasma levels of Hu are shown for four subjects in Fig 3. Subjects 6 and 7 who showed little if any F reticulocyte response and a marked reduction in total reticulocytes had delayed plasma Hu clearance. Subjects A and 12 had normal plasma clearances of Hu, less severe suppression in total reticulocytes (Fig 2), and ten- and fourfold increases in the F reticulocyte level.

Minimal renal dysfunction might prolong clearance of Hu from the plasma and thereby lead to increased renal toxicity. Mean serum creatinine levels during therapy for each subject (range, 0.5 to 1.1) correlated significantly with six-hour plasma Hu levels, $r = .85$, $P = .01$. Moreover, the six-hour level of Hu and the mean serum creatinine levels were negatively correlated with maximal F reticulocyte responses ($r = .80$, $P = .03$; and $r = .70$, $P = .05$).

In vitro analysis. Bone marrow–derived CFU-E colonies were assayed in all five subjects studied at the NIH (Table 1). The F reticulocyte response as measured by the ratio of maximal F reticulocyte levels to pretreatment levels was inversely correlated with the suppression of CFU-E colony growth at two days of therapy. Subject 6, who had the most profound reticulocyte suppression (Fig 2), showed the greatest reduction in CFU-E on day 2. An analysis of data regarding BFU-E colony growth suggests that suppression may also be related to the F reticulocyte response. Subject 10, who showed the highest F reticulocyte response, had no suppression of BFU-E colonies at day 2. Subject 12, who showed an intermediate response, had an early suppression of BFU-E (19%, day 2), but some later recovery (80%, day 7). Subjects 11 and 7, who showed relatively low F reticulocyte responses, showed profound suppression of BFU-E colonies on day 2 and day 7.

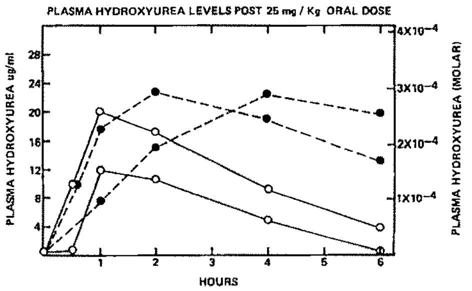

Fig 3 Plasma Hu levels measured following an oral dose of 25 mg/kg Hu. Open circles represent subjects A (peak level, 20 μg/mL) and 12 (peak level, 12 μg/mL), and closed circles represent subjects 6 (peak at four hours, 22 μg/mL) and 7 (peak at two hours, 23 μg/mL).

Table 1. Comparison of F Reticulocyte Increments and CFU-E Colony Formation During Hu Therapy

Subjects	F Reticulocyte Ratio* (Post/Pre)	CFU-E† (%)		BFU-E‡ (%)	
		Day 2	Day 7	Day 2	Day 7
10	4.6	103	—	160	—
12	3.6	82	82	19	80
11	2.1	22	8	26	4
7	1.3	23	6	0	0
6	0.1	2	—	—	—

*Post = maximum F reticulocytes × $10^4/\mu L$ (See Fig 1). Pre = pre-F reticulocytes × $10^4/\mu L$.

†Number of CFU-E colonies expressed as a percentage of day 0 (pretherapy) CFU-E colonies The pretherapy number of CFU-E colonies/10^5 nucleated cells were 107, 78, 314, 60, and 85 for subject 10, 12, 11, 7, and 6, respectively

‡Number of BFU-E colonies expressed as a percentage of day 0 (pretherapy) BFU-E colonies. The pretherapy number of BFU-E colonies/10^5 nucleated cells were 38, 57, 152, and 50 for subjects 10, 12, 11, and 7, respectively

DISCUSSION

In a previous report by Platt et al,[6] two SS subjects given Hu, 50 mg/kg/d divided into three doses for five days, increased F reticulocyte levels without significant suppression of reticulocytes. In this report, eight subjects treated with comparable doses for three to five days showed suppression of total reticulocyte counts, with marked suppression seen in two of our subjects. The number of F reticulocytes after seven days of therapy with Hu increased slightly in six out of eight subjects even though all subjects experienced suppression in total reticulocytes. Even after recovery of the marrow, F reticulocyte levels were not significantly increased. Furthermore, the rapid increase in F reticulocytes (two to three days after starting therapy) previously reported[3,9,10] following 5-aza therapy is not seen in our subjects treated with Hu.

Our subjects showed considerable differences in their F reticulocyte responses to Hu. A clue to the origin of that variability is apparent when serum creatinine and plasma Hu levels are analyzed Minimal renal dysfunction leads to delayed clearance of Hu from the plasma. Previous investigators have shown that peak plasma levels of Hu $>10^{-4}$ mol/L (7.6 μg/mL) will cause marrow cytotoxicity in man.[14] The peak levels obtained in all subjects given a 25-mg/kg test dose of Hu are in the cytotoxic range. In subjects with higher serum creatinine levels (Fig 3), plasma Hu levels remain elevated for a longer period of time, leading to significant marrow suppression and decreased F reticulocyte response.

The differences in the Hu-induced F response of the subjects reported herein and those of Platt et al[5] are unclear. Presumably, the peak drug level after a single 50 mg/kg dose given to our subjects would be much higher and possibly more toxic than the divided doses given by Platt et al. However, when the two subjects (6 and 7) with the greatest toxicity to a single dose of 50 mg/kg/d were given lower doses, both showed suppression of total reticulocyte count levels, and only one showed a marginal increase in F reticulocytes. The two subjects treated by Platt et al were younger than our eight subjects, ages 17 and 23 v ages ranging from 27 to 44 in our subjects. Both of Platt's subjects had normal serum creatine levels, 0.3 and 0.5 (personal communication, Platt). Our data would suggest that these low serum creatine values would favor a higher F reticulocyte response. Finally, preliminary information on two subjects (A and C) with serum creatinine values of 0.6 and 0.9 subsequently treated at Hopkins suggests that less cytoxicity and a more sustained F response may be achieved if the amount of Hu given three days per week is reduced to 20 to 40 mg/kg/d.

This report also indicates that drugs given at doses that caused detectable marrow suppression are unlikely to be of benefit in SS subjects since the result of such suppression is a decrease in F cell production. These observations are important since others[6-8] have suggested that the mechanism of action of 5-aza and Hu is the selective cytotoxic effect on late erythroid progenitors (CFU-E) and subsequent recruitment of high HbF-producing early erythroid progenitors (BFU-E). In a previous report[10] we have shown that CFU-E suppression is not associated with increased F reticulocyte response with 5-aza. In this report we show that patients who had the least measured toxicity to their CFU-E on day 2 of treatment (subjects 10 and 12) had the highest F reticulocyte response. Conversely, the subjects with the most profound decrease in CFU-E at two days of therapy were the ones with the least F reticulocyte response These data along with previous information[10] that shows no cytotoxicity of CFU-Es following 5-aza therapy suggest that selective CFU-E cytotoxicity is not necessary for the early increases in F reticulocytes following 5-aza or Hu.

It is unclear whether 5-aza and Hu increase F cell production in the same way. In those subjects treated with both drugs, the F reticulocyte response is more rapid and consistently higher with 5-aza than with Hu. 5-aza increased F cell production without suppression of CFU-E on day 2 of therapy. In this report the highest response among the patients studied at the NIH was the individual with no detectable suppression of BFU-E or CFU-E. Clearly, cytotoxicity of erythroid precursors is not necessary for a rapid increase in F cell production. Some increase in F cell production, however, may result from drug therapies that selectively inhibit CFU-E and not BFU-E. Unfortunately, our data suggest that Hu treatment is more likely to suppress both CFU-E and BFU-E. Careful adjustment of Hu dosage based on measured plasma levels after a test dose may permit a more selective effect.

Since selective cytoreduction of late erythroid precursors (CFU-E and pronormoblasts) is not associated with increased HbF productions in clinical trials using 5-aza and Hu,[3,5,10] alternative mechanisms must now be considered. Other agents (vincristine, cytosine arabinoside) that perturb cell-cycle kinetics have been associated with increased HbF production.[8,15] We now favor the hypothesis that perturbation of the cell cycle without cell death may in some way change the regulatory patterns that control fetal and adult hemoglobin production. No information is available as yet that indicates how perturbation of the cell cycle might alter gene expression. Perhaps reversible delays in cell division lead to the accumulation of unstable proteins. These proteins may act as trans-acting substances that modulate differential globin gene expression. Further tests are now underway to test several aspects of this general hypothesis.

Neither this study nor previous reports of 5-aza[2,4,9] and Hu[5] indicate that these drugs have therapeutic benefit in SS disease. Further studies are necessary to determine whether lower or less frequent doses of Hu will result in greater F reticulocyte response and less cytotoxicity A previous uncontrolled study[9] showed that prolonged 5-aza therapy can decrease anemia and may decrease the severity and frequency of vaso-occlusive crisis Controlled clinical trials are necessary to determine the efficacy of 5-aza or Hu therapy, but it is unlikely that such trials can be carried out until the carcinogenicity of the two drugs can be determined more completely.[16,17] This report indicates that Hu is also more difficult to use because of the apparently narrow window between cytotoxicity and the desired effect on increased HbF production.

ACKNOWLEDGMENT

We express our appreciation to Patricia Griffith and Martha Moyer for assisting in the clinical care of our subjects

Diffuse Large Cell Lymphoma in a Patient With Hairy Cell Leukemia: Immunoglobulin Gene Analysis Reveals Separate Clonal Origins

By James R. Downing, Carlo E. Grossi, Carl T. Smedberg, and Peter D. Burrows

A 75-year-old man with hairy cell leukemia (HCL) was found to have an immunoblastic lymphoma of the small bowel. Immunologic and genotypic characterization of these neoplasms revealed both the HCL and the immunoblastic lymphoma to be of the B cell lineage. The HCL expressed the HCL-associated antigens detected by the monoclonal antibodies HC-1 and HC-2, whereas the immunoblastic lymphoma failed to react with these antibodies. In addition, surface immunoglobulin light chains could not be accurately determined for the hairy cells, whereas the immunoblastic lymphoma was shown to express only κ immunoglobulin light chains. These immunophenotype differences were compatible with either the clonal evolution of the HCL into the immunoblastic lymphoma or a separate clonal origin for these two neoplasms. An analysis of tumor DNA by Southern blot hybridization revealed different heavy-chain and κ light-chain gene rearrangements in these two malignancies. Thus the occurrence of the large cell lymphoma most likely represents the emergence of a second clonally unrelated B cell malignancy.

© 1986 by Grune & Stratton, Inc.

HAIRY CELL LEUKEMIA (HCL) is a chronic low-grade malignant lymphoproliferative disease characterized by pancytopenia, splenomegaly, and morphologically distinct lymphocytes in the bone marrow, spleen, and occasionally the blood.[1-4] Considerable controversy has existed over the lineage of the neoplastic cells of HCL.[5-16] However, recent analyses of the immunoglobulin genes in 19 cases of HCL have revealed rearrangements of a heavy-chain gene locus and at least one light-chain gene locus in each case, confirming the B cell nature of this lymphoproliferative disorder.[17,18] Unlike other chronic B cell neoplasms, HCL rarely shows histologic progression to a high-grade non-Hodgkin's morphology Occasional instances of the coexistence of HCL and diffuse histiocytic lymphoma have been reported.[19-22] It has been suggested that this coexistence represents the histologic progression or clonal evolution of the hairy cell leukemia into the diffuse histiocytic lymphoma, although little evidence in support of this contention has been presented. In this report we present the detailed immunologic and molecular genetic analysis of a patient with HCL who early in his course was found to have a large cell immunoblastic lymphoma. Our results suggest that the immunoblastic lymphoma represents the emergence of a second malignant B cell clone differing from the original B cell clone of the HCL

CASE REPORT

The patient, a 75-year-old man, had a nine-month history of refractory anemia. A bone marrow biopsy performed in January 1984 was interpreted as representing refractory anemia with excess blasts. The patient was treated with oxymethalone 100 mg daily and prednisone 60 mg daily for 6 weeks with little response In June 1984 he was referred to the University of Alabama Hospitals with general malaise, easy fatigability, abdominal pain, fevers, and a productive cough. On physical examination he was afebrile and mildly cachectic with hepatosplenomegaly and right upper lobe crackles. Laboratory values included a hemogloblin level of 9.7 mg/dL; a platelet count of 94,000/mm³; a white blood cell count of 800/mm³, of which 20% were small lymphocytes; and a serum bilirubin level of 2.1 mg/dL. Chest x-ray demonstrated a right upper lobe infiltrate. A bone marrow biopsy showed a diffuse infiltration of small mononuclear cells along with myeloid hyperplasia and immaturity. This biopsy was again interpreted as representing a myelodysplastic condition, and the patient was successfully treated for his pneumonia with Mezlocillin, Tobramycin, and Erythromycin. Four months later the patient was readmitted for progressive general malaise, easy fatigability, lower abdominal pain, fevers, an 8-pound weight loss, and progressive splenomegaly. Laboratory values revealed a hemoglobin level of 10.8 mg/dL; a platelet count of 37,000/mm³, and a white blood cell count of 800/mm³, of which 83% were small lymphocytes. A bone marrow biopsy showed a diffuse infiltration of small lymphoid cells and was diagnosed as HCL. The patient underwent a therapeutic splenectomy in late October 1984 The resected spleen weighed 2,025 g and showed histologic features consistent with involvement by HCL. At surgery a 5-cm mass was discovered in the jejunum with extension into the mesentery, and this was resected. Histologically, the small-bowel lesion showed infiltration by large pleomorphic lymphocytes consistent with a non-Hodgkin's lymphoma of high-grade malignancy (diffuse histiocytic lymphoma, Rappaport Classification; malignant lymphoma, large cell, immunoblastic, Working Formulation). The patient was treated with Cytoxan 697 mg, Adriamycin 46 mg, Oncovin 1 mg, and prednisone 50 mg daily for five days. Despite three subsequent courses of chemotherapy, hepatomegaly and pancytopenia with circulating hairy cells persist

MATERIALS AND METHODS

Morphology and cytochemistry Portions of the biopsy tissues obtained after appropriate informed consent were fixed in phosphate-buffered formalin and embedded in paraffin, and sections were stained with hematoxylin and eosin (H & E) Peripheral blood smears were stained with Wright-Giemsa stain. Bone marrow aspirates were stained with Wright-Giemsa stain, periodic acid-Schiffs reagent, or acid phosphatase by standard techniques.[23] The tartrate-resistent acid phosphatase (TRAP) activity was determined by the addition of a tartaric acetate buffer to the incubation mixture [24]

Immunologic characterization Mononuclear cells were isolated from heparinized blood samples by Ficoll-Hypaque (Pharmacia Fine Chemicals, Piscataway, NJ) density gradient centrifugation Cell suspensions from bone marrow aspirate and bowel tissue were obtained by gentle homogenization and subsequently freed of erythrocytes, mature granulocytes, and dead cells by Ficoll-Hypaque density gradient centrifugation

Surface marker expression was determined on viable cells using mouse monoclonal antibodies followed by fluorescein isothiocyanate–labeled goat antimouse immunoglobulin (Southern Biotechnology Associates, Birmingham, Ala.). Positive cells were evaluated by both fluorescence microscopy and flow cytometry (FACS-Analyzer, Becton-Dickinson, Sunnyvale, Calif).

Anti–T cell antibodies of the Leu series and anti-HLA-DR were provided by Becton-Dickinson (Mountain View, Calif). The pan-B monoclonal antibody B-1 was obtained from Coulter (Hialeah, Fla), and the anti-immunoglobulin reagents with specificities for human light or heavy chains were purchased from Southern Biotechnology Associates. Monoclonal antibodies HC-1 and HC-2 with specificities for hairy cells were the kind gift of Dr David Posnett (Rockefeller University, New York)[25]

Gene rearrangement studies High molecular weight DNA from peripheral blood mononuclear cells or from fresh cell suspensions prepared from the small-bowel mesenteric mass was isolated according to standard procedures.[26] Twenty micrograms of the DNA was digested (3U/μg) with the restriction endonucleases *Bam*HI or *Eco*RI (IBI, New Haven, Conn) and size-fractionated on 0 7% agarose gels The DNA fragments were transferred out of the gel to Zetabind® filters (AMF, Cuno, Meriden, Conn) as described by Southern.[27] Filters were hybridized with nick-translated ^{32}P-radiolabeled human immunoglobulin gene DNA fragments with specific activities of 1×10^8 cpm/μg DNA. The probe for the human heavy-chain locus consisted of a 6 5-kb *Hin*dIII/*Bam*HI genomic J_H insert. This probe recognizes rearrangements in either *Bam*HI- or *Eco*RI-digested DNA. Rearrangements of κ genes were detected within *Bam*HI-digested DNA by using a 2.5-kb genomic *Eco*RI $C\kappa$ probe. Rearrangements of λ genes were detected within *Eco*RI-digested DNA by the combined 7 6-kb genomic *Eco*RI C_λ (Mcg) fragment and a 6 0-kb genomic *Eco*RI C_λ (Ke$^-$Oz$^-$) fragment. The structure of these probes is fully described elsewhere.[28-30] Hybridization reactions were carried out using 50% formamide and 10% dextran sulfate at 42°C. After extensive washing at the appropriate stringency, the filters were exposed to Kodak XAR-5 film using a single intensifying screen for 48 to 144 hours at −70°C.

RESULTS

Morphology and cytochemistry. Sections of the initial bone marrow biopsy revealed an increase in immature mononuclear cells of undetermined lineage along with myeloid and megakaryocytic hyperplasia. Although not diagnostic, the distribution of the mononuclear cells and their cytologic features were in retrospect suggestive of HCL. All subsequent bone marrow biopsies are in retrospect diagnostic of involvement by hairy cell leukemia. In these biopsies the cellularity was 80%. There was a diffuse infiltration of the marrow by small mononuclear cells having irregular bean-shaped nuclei, irregularly clumped chromatin, and a large rim of pale eosinophilic cytoplasm frequently showing retraction artifacts. Mitoses were extremely rare. Occasional clusters of normal maturing myeloid and erythroid elements were identifiable. The mononuclear cells in the bone marrow aspirate had the typical morphology of hairy cells with abundant basophilic cytoplasm, marked irregularity of the cytoplasmic borders, and small central hyperchromatic nuclei. Acid phosphatase stains of the bone marrow aspirate revealed positively staining intracytoplasmic granules in all of the mononuclear cells with no loss in acid phosphatase activity after exposure to tartrate.

The spleen weighed 2,025 g. The cut surface was firm with a focal micronodular texture. Histologically, the red pulp of the spleen was infiltrated by mononuclear cells similar to those seen in the bone marrow (Fig 1). The cells had abundant pale cytoplasm and small irregular nuclei and were frequently separated from each other by clear spaces. This mononuclear infiltrate focally extended into the white pulp. Numerous small blood lakes typical of HCL were identified within the red pulp of the spleen. At the time of splenectomy, a peripheral blood smear showed 20% lymphocytes that had the cytologic features of hairy cells.

A 5-cm segment of jejunum was removed during laparotomy There was marked thickening of the bowel wall with loss of the normal mucosal folds and marked mucosal thinning. The bowel wall was infiltrated by large pleomorphic mononuclear cells with large irregular nuclei, peripheral condensation of the chromatin, prominent eosinophilic nucleoli, and abundant amphophilic cytoplasm (Fig 2). Numerous mitotic figures were identified along with extensive single cell necrosis. The histologic features of this bowel lesion were diagnostic of a diffuse large cell non-Hodgkin's lymphoma (malignant lymphoma, large cell, immunoblastic, Working Formulation).

Immunologic characterization. Data on the expression of immunoglobulin products and other lymphocyte surface markers are summarized in Table 1. Approximately 20% of the cells in the peripheral blood and bone marrow aspirate were leukemic. The leukemic cells in these samples expressed the B-1 and HLA-DR antigens as well as the HCL-associated antigens detected by the monoclonal antibodies HC-1 and HC-2.[25] Analysis of surface immunoglobulin expression on peripheral blood mononuclear cells was equivocal with both κ- and λ-bearing lymphocytes present. A restricted expression of the γ heavy-chain isotype was detected, suggesting a probable B cell clone. The lymphoma cells from the small-bowel mass were shown to consist of a monoclonal B cell population that expressed surface μ and δ heavy chains and κ light chains. These cells were negative for antigens detected by the monoclonal antibodies HC-1 and HC-2.

Gene rearrangement studies. Studies of the arrangement of the immunoglobin heavy- and light-chain genes were performed on peripheral blood mononuclear cells (PBMC), and a mononuclear cell suspension prepared from the small-bowel mass. Utilizing *Bam*HI-digested DNA and a J_H probe, a single but different clonal rearrangement of the immunoglobulin heavy-chain gene locus was detected in each sample (blood, 19 kb; bowel, 11 kb; Fig 3). The intensity of the clonally rearranged band detected in the PBMC was less than the germ-line band and is consistent with a leukemic clone comprising a minority of the total PBMC. Analysis of the κ immunoglobulin light-chain locus within *Bam*HI-digested DNA utilizing a C_κ probe also revealed a single but different clonal rearrangement in each sample (blood, 6 kb; bowel, 18 kb; Fig 3). The λ light-chain gene locus as analyzed within *Eco*RI-digested DNA was in the germ-line configuration in both samples (Fig 3). These results indicate that although the expressed light-chain isotype within these two B cell malignancies are the same, the immunoglobulins are

DISCUSSION

This patient had the typical clinical and histopathologic features of HCL. The leukemic cells in both blood and bone marrow expressed B cell–associated antigens and the hairy cell–associated antigens detected by the monoclonal antibodies HC-1 and HC-2. In addition, mononuclear cells from bone marrow were positive for tartrate-resistant acid phosphatase. The B cell nature of this malignancy was confirmed by the presence of clonal rearrangements of the immunoglobulin heavy- and light-chain gene loci, a finding consistent with results from two recent studies on HCL.[17,18]

Although the occurrence of a second malignancy in patients with HCL is not uncommon, the occurrence of a high-grade non-Hodgkin's lymphoma as described in this case is extremely rare.[20,31-33] Several case reports of patients with HCL and large cell lymphoma have been published.[19-22] In each case the diagnosis of large cell lymphoma was based primarily on the interpretation of histologic material. Several of these reports suggest that the large cell lymphoma represented a blastic transformation of the hairy cells, a situation similar to the Richter transformation of chronic lymphocytic leukemia.[34,35] Davis et al[22] have recently described a case of HCL and large cell lymphoma in which both malignancies expressed tartrate-resistant acid phosphatase. Based on these data, the authors suggested that the large cell lymphoma represented the clonal evolution or blastic transformation of the original HCL. Thus, although supportive data for the idea of the clonal evolution of hairy cell leukemia into a high-grade lymphoid malignancy exist, no detailed analysis of the relationship of the malignant clones of the low- and high-grade tumors is presently available.

In this study we performed immunophenotyping and molecular genetic analysis of the malignant clones in a patient with HCL and immunoblastic lymphoma. The immunologic and genetic characterization of these two malignancies demonstrated phenotypes and genotypes that were consistent with B cell HCL and B immunoblastic lymphoma. Although both malignancies were of the B cell lineage, immunophenotypic differences between these malignant clones existed. The absence of the antigens detected by HC-1 and HC-2 on the immunoblastic lymphoma and the clear ability to detect its surface immunoglobulin phenotype could be compatible with the clonal evolution of the HCL into immunoblastic lymphoma. If this had been the case, both the HCL and the immunoblastic lymphoma cells would have had identical heavy- and light-chain immunoglobulin gene rearrangements. However, Southern blot hybridization analyses revealed different heavy- and light-chain gene rearrangements in these two malignancies (Fig 3). These results are consistent with the large cell lymphoma representing the emergence of a second B cell malignancy. The possibility that these two B cell malignancies are related at the stage of a common premalignant B cell precursor cannot be excluded from these data.

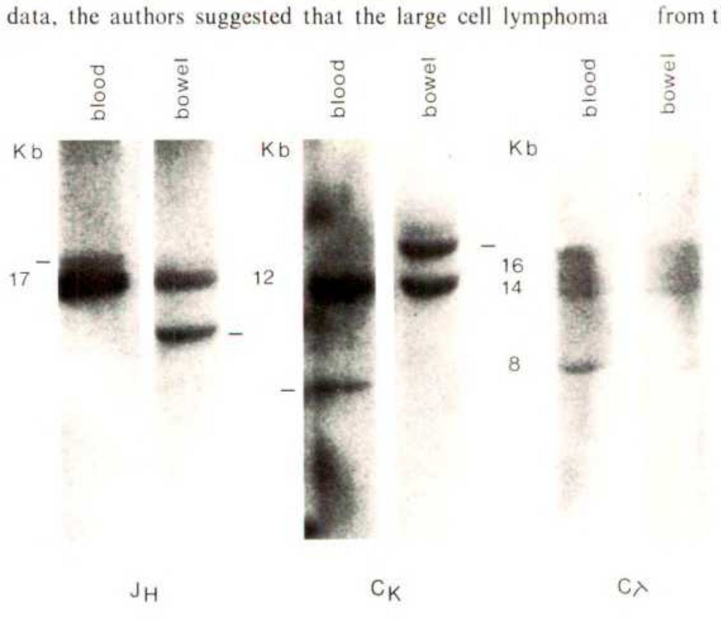

Fig 3. Southern blot analysis of immunoglobulin genes in peripheral blood mononuclear cells ("blood") and small-bowel mononuclear infiltrate ("bowel"). For the heavy-chain (J_H) and κ light-chain (C_κ) gene analysis, the DNA was cleaved with the restriction endonuclease *Bam*HI. For λ light-chain (C_λ) gene analysis, the DNA was cleaved with the restriction endonuclease *Eco*RI. Germ-line bands are indicated by their corresponding size in kilobases (kb). Lines indicate the position of rearranged bands.

The finding that the so-called blastic transformation or histologic progression of a low-grade lymphoproliferative lesion in fact represents the emergence of a second tumor is not without precedent. A recent study on a patient with Richter's transformation revealed that the high-grade pleomorphic tumor and the chronic lymphocytic leukemia expressed different light-chain isotypes and had different heavy- and light-chain gene rearrangements.[36] In addition, an examination of immunoglobulin gene rearrangements in seven cases of low-grade non-Hodgkin's lymphoma that showed histologic progression on a second biopsy revealed that in three cases the high-grade tumor represented the emergence of a new, genetically distinct clone.[37] Our findings in conjunction with these suggest that the occurrence of a second B cell malignancy in a patient with a preexisting B cell tumor may be a more frequent event than is presently appreciated. Detailed immunophenotyping and molecular genetic analysis of additional cases of patients with HCL and lymphoma will be needed to determine if HCL can ever show true clonal evolution or blastic transformation into a high-grade tumor.

ACKNOWLEDGMENT

The authors thank Dr P Leder for providing the human J_H, C_κ, C_λ (Mcg), and C_λ (Ke$^-$ Oz$^-$) immunoglobulin gene probes and Doris Jones for typing the manuscript.

Carbonyl Iron Therapy for Iron Deficiency Anemia

By Victor R. Gordeuk, Gary M. Brittenham, Christine E. McLaren, Margaret A. Hughes, and Louise J. Keating

To determine if elemental carbonyl iron powder is safe and effective therapy for iron deficiency anemia, 20 nonanemic and 32 anemic volunteers were studied. Single doses of 1,000 to 10,000 mg of carbonyl iron (15 to 150 times the 65 mg of iron in the usual dose of ferrous sulfate) were tolerated by nonanemic volunteers with no evidence of toxicity and only minor gastrointestinal side effects. Anemic volunteers (menstruating women who had previously donated blood) were treated with several regimens providing 1,000 to 3,000 mg of carbonyl iron daily in one to three doses for 8 to 28 days. After 12 weeks anemia was corrected in 29 of 32 patients, and serum ferritin was greater than 12 μg/L in 14. Hemoglobin regeneration proceeded at a rate similar to that described for therapy with oral iron salts and parenteral iron dextran. There was no evidence of hematologic, hepatic, or renal toxicity, but mild gastrointestinal side effects occurred in a majority of anemic volunteers. Carbonyl iron is an effective, inexpensive treatment for iron deficiency anemia, is accompanied by tolerable side effects and may have an advantage over therapy with iron salts by substantially reducing or eliminating the risk of iron poisoning in children.

© 1986 by Grune & Stratton, Inc.

IRON DEFICIENCY is the most common cause of anemia in the world.[1-3] For the past half century the standard therapy for iron deficiency anemia has been ferrous salts.[4] Recently, however, Crosby suggested that carbonyl iron may be "an ideal therapeutic agent, effective yet lacking in toxicity."[5] Ionic (Fe^{2+}) iron salts such as ferrous sulfate are effective in the correction of iron deficiency anemia, but their use has disadvantages, including the risk of accidental iron poisoning in small children, the occurrence of side effects, and the prolonged duration of treatment required to correct anemia and replenish iron stores. Tablets containing ferrous iron are the second most common cause (after aspirin) of accidental poisoning among small children, leading to as many as 500 hospitalizations and several deaths per year.[5] Side effects with a standard dose of ferrous sulfate occur in 10% to 15% of patients when compared to placebo[6] and result in difficulty in maintaining motivation of patients to comply with therapy. Restoration of hemoglobin to normal with ferrous sulfate requires 3 to 6 months of treatment; replenishment of body iron stores requires therapy for an additional 2 to 4 months.[6-8]

Elemental uncharged iron powder was used early in this century for treatment of iron deficiency anemia and was nontoxic when compared to ferrous salts.[9] However, this elemental iron preparation, which was produced by a hydrogen-reduction process, had poor bioavailability when compared to ferrous salts, possibly due to the relatively large size of the iron particles of about 50 μm[5] and relatively limited reactive surface area.[10] Since then the elemental iron preparation known as carbonyl iron powder has been introduced.[11] "Carbonyl" does not refer to the composition of the iron particles but rather to the manufacturing process in which the controlled heating of vaporized iron pentacarbonyl leads to the deposition of uncharged, elemental iron as submicroscopic crystals that form microscopic spheres of less than 5 μm in diameter The preparation is more than 98% pure.[12] As a food additive, carbonyl iron has been shown to be well absorbed and utilized for hemoglobin synthesis, both in experimental animals and in humans.[12-16] In Sweden, where about half of the fortification iron now used is carbonyl iron, the high bioavailability of this form of iron has been considered one factor contributing to a reduction in iron deficiency.[17] Recent studies in rats have clarified the mechanism of absorption of the finely particulate carbonyl iron now available (Huebers et al, unpublished observations). The conversion of particulate carbonyl iron to soluble ionized iron by stomach acid was a prerequisite for absorption and was limited by the rate of gastric acid production. Subsequent uptake by the intestinal mucosa and absorption were similar with equivalent doses of ferrous iron, although absorption of carbonyl iron occurred over a longer interval. In these studies, the bioavailability of carbonyl iron and ferrous iron was similar with doses of 0.2 to 80 mg Fe/kg body weight.

While not previously used pharmacologically, several studies suggest that as a therapeutic agent, carbonyl iron powder may effectively correct iron deficiency anemia yet be considerably less toxic than iron salts. In rats with iron deficiency anemia, carbonyl iron has been used successfully to correct anemia and replace iron stores.[12,18] In humans, as in dogs, rabbits, and guinea pigs, the estimated lethal dose of oral ferrous sulfate is about 200 mg Fe/kg body weight.[19-21] Human volunteers have taken oral doses of 10,000 mg of carbonyl iron (about 140 mg Fe/kg) "without deleterious effect."[5] Formal toxicity studies of carbonyl iron in rats and guinea pigs found that the LD_0 (the dose that all animals survive) was 10,000 to 15,000 mg Fe/kg and the lethal dose (LD_{100}) was 50,000 to 60,000 mg Fe/kg.[11] These differences in toxicity may be related to differences in the requirements for absorption of iron in the carbonyl and ferrous forms. Fatal amounts of iron may be absorbed through an anatomically intact intestinal mucosa.[20] With ferrous sulfate, all the iron in a soluble ionized form is potentially available for absorption. With carbonyl iron, however, only that fraction solubilized by gastric acid is available for absorption; in addition, the rate of solubilization is restricted by the rate of gastric acid production (Huebers et al, unpublished observations).

To determine if carbonyl iron is safe and effective for the treatment of iron deficiency anemia in humans, we carried out studies of dosage, toxicity, and side effects for carbonyl iron in 20 nonanemic volunteers and in 32 patients with iron deficiency anemia.

MATERIALS AND METHODS

The use of carbonyl iron was approved by the Committee on Human Investigation at Cleveland Metropolitan General Hospital Studies were conducted under the provisions of a claimed investigational exemption for a new drug (IND No. 22389) of the Food and Drug Administration. All subjects participating in the study were advised of the procedures and attendant risks in accordance with our institution's guidelines and gave informed consent.

Healthy Volunteers

Twenty healthy adult nonanemic volunteers were given orally a reference solution containing 498 mg of ferrous sulfate (100 mg Fe^{2+}) and 100 mg of ascorbic acid in .001 N hydrochloric acid, and at approximately 1-week intervals thereafter various doses of carbonyl iron powder in gelatin capsules were administered orally The doses of iron were given after an overnight fast, and the fast was continued for three to four hours after iron ingestion Ascorbic acid was given along with the ferrous sulfate to permit comparison of our results with previous studies examining the relationship between increase in serum iron concentration and the total amount of iron absorbed [22] Blood samples were drawn initially and at intervals from ½ hour to 24 hours after each dose of ferrous sulfate or carbonyl iron to monitor serum iron, total iron binding capacity (TIBC), percent saturation of TIBC and serum ferritin and to assess liver function as measured by bilirubin, serum glutamic oxaloacetic transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT), and alkaline phosphatase, and renal function as measured by serum creatinine. Five volunteers received carbonyl iron in single incremental doses of 100 mg, 1,000 mg, and 5,000 mg at approximately 1-week intervals, four of these volunteers also received a 10,000 mg dose of carbonyl iron. Blood samples were drawn at 0, ½, 1, 2, 3, 4, 5, and 6 hours following the doses of iron Nineteen volunteers received a 3,000-mg dose of carbonyl iron at approximately 1 week or more after the reference dose of ferrous sulfate, and blood samples were drawn at 0, 3, 6, 12, and 24 hours following the doses of iron. Side effects were monitored on a standardized form that included space to record constipation, diarrhea, heartburn, nausea, abdominal cramps, headache, weakness, and "unpleasant taste." The increase in serum iron was used as an indicator of iron absorption

Volunteers With Iron Deficiency Anemia

Thirty-two volunteers were recruited from blood donors to the Northern Ohio Red Cross who met the following criteria: (1) menstruating nonpregnant women between the ages of 18 and 40 years and (2) deferral for repeat blood donation because of hematocrit <38% They received one of several short-term courses of carbonyl iron powder (shown later in Table 2) Gelatin capsules containing either 500 or 1,000 mg of carbonyl iron were used Blood samples were drawn at 0, 1, 3, 6, 9, and 12 weeks for determination of free erythrocyte protoporphyrin (FEP), serum ferritin, serum iron, TIBC, percent saturation of TIBC, and complete blood count (CBC) including hemoglobin, mean cellular volume (MCV), white blood cells (WBC), and platelets. In addition, serum bilirubin, SGOT, SGPT, alkaline phosphatase, and creatinine were measured at 0, 1, and 3 weeks. Side effects were recorded on standard forms as described above at weeks 1 and 3 of the study

Estimation of iron absorption. An estimate for the absorption of carbonyl iron was made by calculating the increase in hemoglobin iron and storage iron between weeks 0 and 12 of the study and using the following equation

Total amount of iron absorbed = increase in hemoglobin iron + increase in storage iron

The increase in hemoglobin iron was calculated using the following equation

Increase in hemoglobin iron = increase in hemoglobin (g/100 mL) × 3.47 mg Fe/g hemoglobin × assumed body weight of 60 kg × 60 mL blood/kg body weight

The increase in storage iron was calculated by assuming that 1 μg/L of serum ferritin represents approximately 10 mg of storage iron if the serum ferritin is greater than 12 μg/L[23] and that storage iron is absent if the serum ferritin is less than 12 μg/L.[24,25] Since at week 0 the serum ferritin was less than 12 μg/L in all but one of our patients, the equation was the following.

$$\text{Increase in storage iron (mg)} = [\text{serum ferritin } (\mu g/L) \text{ at week } 12] - 12\,\mu g/L] \times 10$$

In these calculations neither menstrual loss nor dietary absorption of iron was taken into consideration.

Laboratory Methods

Serum iron, TIBC, and percent saturation of TIBC were determined by the methods of the International Committee for Standardization in Hematology (ICSH).[26] Serum ferritin was analyzed using FER-IRON immunoradiometric assay kits (Ramco Laboratories, Inc, Houston). FEP was measured with a ZnP model 4000 Hematofluorometer (Environmental Sciences Associates, Inc., Bedford, Mass). CBC was determined with a Coulter Counter Model Z_F or a Coulter Counter Model S-Plus II (Coulter Electronics, Inc, Hialeah, Fla). Serum bilirubin, SGOT, SGPT, alkaline phosphatase, and creatinine were measured by an automated method using the Parallel Analytical System (American Monitor Corp, Indianapolis).

Statistical Methods

Data were analyzed using BMDP computer programs.[27]

Studies in nonanemic volunteers. For each of five volunteers given incremental doses of carbonyl iron (Fig 1), the mean change in serum iron achieved over three to six hours after each dose of carbonyl iron was examined using a one-way repeated measures analysis of variance. To test the hypotheses that changes in serum iron increased with increasing doses of carbonyl iron, one-sided paired *t* tests were applied [28] To assure detection of an overall significance level of 05, Bonferroni significance levels were used for individual tests.[29] The mean changes in serum iron over 24 hours after ingestion of 100 mg of ferrous sulfate and 3,000 mg of carbonyl iron in 19 normal volunteers (Fig 2) were compared using repeated measures analysis of variance followed by two-sided paired *t* tests. The binomial test[30] was used to compare the number of overall gastrointestinal side effects experienced by 18 volunteers following a single dose of ferrous sulfate and carbonyl iron. It was also used to compare the numbers of volunteers experiencing individual side effects after each dose of iron.

Studies in anemic volunteers Paired *t* tests were used to compare the mean values for hemoglobin, MCV, FEP, serum ferritin, serum iron, TIBC, and percent saturation of TIBC before and 12

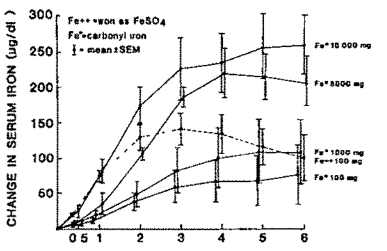

Fig 1. Change in serum iron over six hours following a reference dose of ferrous sulfate and incremental doses of carbonyl iron. N = 5 for all curves except for 10,000-mg dose of carbonyl iron, N = 4. Statistical significance: 1,000 mg and 100 mg, $P = .011$; 5,000 mg and 100 mg, $P = .0004$; 10,000 mg and 100 mg, $P = .0003$; 5,000 mg and 1,000 mg, $P = .0004$; 10,000 mg and 1,000 mg, $P = .0001$.

weeks after carbonyl iron treatment for 32 anemic volunteers (Table 1) Separate one-way analysis of variance procedures followed by pairwise independent sample *t* tests were used to compare the results of the six treatment regimens shown in Table 2 The Bonferroni multiple comparisons procedure was used to assure detection of an overall significance level of 05. The same methods were used to compare the rates of hemoglobin regeneration for volunteers with three levels of initial hemoglobin concentration Pearson's *r* and regression analysis were used to examine the linear relationship between percentage absorption and log cumulative dose of carbonyl iron.[31]

RESULTS

Healthy Volunteers

Figure 1 shows mean response in serum iron over six hours for incremental doses of carbonyl iron alone and a reference dose of 100 mg of iron as ferrous sulfate plus 100 mg ascorbic acid in five healthy volunteers. It should be noted that addition of ascorbic acid to the dose of ferrous sulfate would be expected to enhance iron absorption and to favor ferrous sulfate as far as the magnitude of the increase in serum iron is concerned. The mean (±SEM) maximal increase (141 ± 25 μg/dL) after the reference dose of ferrous sulfate occurred at three hours. This increment was slightly higher than the mean increase of 110 μg/dL reported by Ekenved et al,[22] which corresponded to a whole body absorption of 8.2 mg iron as determined by whole body counting. With an equivalent dose of 100 mg of carbonyl iron, the rise in serum iron was less abrupt but more sustained, with the maximal increase occurring at the end of the six-hour period of observation The rise in serum iron following a dose of carbonyl iron increased progressively with incremental doses of 100, 1,000, 5,000, and 10,000 mg of carbonyl iron. However, in no case was the iron-binding capacity of the serum exceeded. Because of the differences in the pattern of absorption with carbonyl iron and with the reference dose of ferrous sulfate, it was not possible to estimate the whole body absorption of the various doses of carbonyl iron from the serum iron studies or to compare the absorption of the two forms of iron directly.

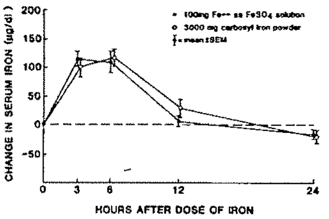

Fig 2. Change in serum iron over 24 hours following 100 mg of iron as ferrous sulfate and 3,000 mg of carbonyl iron; N = 19.

Table 1. Short-Term Carbonyl Iron Therapy for Iron Deficiency Anemia

	Normal	Week 0	Week 12	*P*
Hemoglobin (g/dL)	12 0–16 0	10 8 ± 2	12.9 ± 1	0001
MCV (fL)	81 0–99 0	80 2 ± 1 2	88 3 ± 6	.0001
FEP (μg/dL whole blood)	10–35	48 ± 3	27 ± 1	0001
Serum ferritin (μg/L)	12–250	5.0 ± 5	15 7 ± 1 8	0001
Serum iron (μg/dL)	60–200	71 ± 10	82 ± 6	3652
TIBC (μg/dL)	250–435	417 ± 10	356 ± 9	0001
% Saturation	16–50	17 ± 2	23 ± 2	0559

N = 32 Values shown are mean ± SEM.

Mean responses in serum iron over 24 hours in 19 healthy volunteers after a reference dose of 100 mg of iron as ferrous sulfate plus 100 mg ascorbic acid and after 3,000 mg of carbonyl iron alone are shown in Fig 2. Mean maximal increases in serum iron were nearly the same following both types of iron. The mean (±SEM) maximal increase (115 ± 13 μg/dL) after ferrous sulfate occurred at three hours, while the mean maximal increase (116 ± 16 μg/dL) after carbonyl iron occurred at six hours. No samples were obtained over the next six-hour period, but no statistically significant differences between the two iron preparations were found ($P > .16$) either during the first six hours or during the last 12 hours of observation.

Side effects, including gastrointestinal symptoms and an unpleasant taste sensation, were reported by most volunteers both after 100 mg of Fe^{2+} as ferrous sulfate and after 3,000 mg of carbonyl iron, as depicted in Table 3; these were considered mild by the individuals. Side effect information after carbonyl iron was not available for one of the volunteers. With carbonyl iron the unpleasant taste sensation seemed to be due to eructation. Although overall gastrointestinal ($P = .172$) and other side effects were not statistically different between the two iron preparations, a significantly greater incidence of diarrhea and of abdominal cramping was seen with carbonyl iron. There was no evidence of hepatic or renal toxicity as measured by individual and mean values for serum bilirubin, SGOT, SGPT, alkaline phosphatase, and creatinine drawn initially and at 24 hours.

Volunteers With Iron Deficiency Anemia

Figure 3 and Table 1 depict response to therapy in all 32 anemic volunteers monitored for a 12-week period after starting a course of carbonyl iron treatment lasting from 7 to 28 days and ranging from 1,000 to 3,000 mg per day in single or divided doses. Mean hemoglobin concentration rose to within normal values by the third week and continued to rise throughout the observation period. Mean MCV and FEP returned to normal. All of these changes were statistically

Table 2. Treatment Regimens Used for Iron Deficiency Anemia

Group	Regimen	N	Cumulative Dose of Carbonyl Iron (mg)	Hemoglobin (g/dL)		Ferritin (µg/L)		Estimated Amount of Iron Absorbed (mg)			Amount of Iron Absorbed per Day (mg)	Estimated Absorption of Carbonyl Iron (%)

significant. Mean serum iron and mean percent saturation of the TIBC did not change significantly during the study. Mean ± SEM serum ferritin concentration, which was 5.0 ± 5 µg/L initially, rose during carbonyl iron therapy to a peak value of 40.0 ± 4 6 µg/L at week 1 and then declined to a final value of 15.7 ± 1.8 µg/L at week 12, which was significantly greater than the initial concentration. At the end of the study period, hemoglobin was normal (greater than 12 0 g/dL) in 29 of the 32 volunteers, and serum ferritin was greater than 12 µg/L in 14 of the 32 volunteers. Mean serum ferritin in these 14 patients was 26 ± 2 µg/L. Of the 14 patients with normal ferritin at the end of the study, 12 had initial hemoglobin of >11.0 g/dL.

The responses in mean hemoglobin and serum ferritin and estimates of the mean amounts of iron absorbed for each of six different regimens of short-term carbonyl iron therapy used in the anemic volunteers is shown in Table 2. Although the final hemoglobin concentrations were similar among the groups, there were significant differences in the final serum ferritin concentrations. In group VI, which received the largest dose of iron for the longest period of time, serum ferritin was significantly higher than in group V. In group VI hemoglobin was normal and serum ferritin was >12 µg/L in all volunteers after 4 weeks of carbonyl iron therapy.

Hemoglobin regeneration. The response to carbonyl iron therapy as measured by daily increase in hemoglobin concentration was calculated for each patient. The rate of rise in hemoglobin varied according to the initial hemoglobin concentration but not the treatment protocol. (1) With an initial hemoglobin of 8.9 to 10.0 g/dL, the mean daily increment (±SEM) in hemoglobin was 0.11 ± .01 g/dL during the first 3 weeks of the study when carbonyl iron was taken for all or part of this time. (2) With an initial hemoglobin of 10.0 to 11.0 g/dL, the mean daily response in the first 3 weeks was 0.09 ± .01 g/dL, and (3) with an initial hemoglobin of 11.0 to 12.0 g/dL, it was .04 ± .01 g/dL. The hemoglobin regeneration rate for case 3 was significantly lower than for cases 1 (*P* = .0007) and 2 (*P* = .0004) As mentioned previously, the mean hemoglobin concentration continued to rise throughout the study period, even following the completion of carbonyl iron therapy. During weeks 6 to 12, when carbonyl iron therapy had been completed for at least 2 weeks, there was a mean daily increase in hemoglobin of .01 ± .01 g/dL; this increment was seen for all three categories of initial hemoglobin concentration.

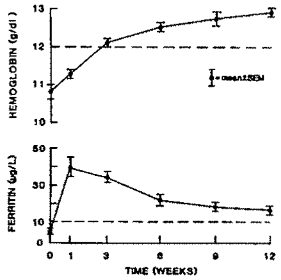

Fig 3. Change in hemoglobin and serum ferritin concentrations with short-term carbonyl iron therapy in anemic volunteers; N = 32.

Absorption of carbonyl iron. An estimate of the total and daily amount of carbonyl iron absorbed during the study was made for each patient, as shown in Table 2. Estimated total amounts of iron absorbed for the various treatment groups ranged from mean (±SEM) values of 232 ± 64 to 410 ± 57 mg, but there were no statistically significant differences among the six groups. However, when expressed as the amounts of iron absorbed per day, the range was 12 ± 3 to 47 ± 9 mg, and there were significant differences among the groups. Group I, with the shortest duration of therapy, had a greater estimated absorption per day than groups IV, V, and VI, and group II had a greater estimated absorption than group IV There were also significant differences in estimated percentage absorption of the cumulative dose of carbonyl iron among the groups. Group I and II, which received the smaller cumulative doses, had a greater estimated percent absorption than group VI, which received the largest cumulative dose. Analysis of the estimates of percent absorption for all 32 volunteers revealed a significant negative correlation with the log of the cumulative dose of carbonyl iron ($r = -.62$; $P < .001$).

Side effects and toxicity. Side effects, shown in Table 3, were recorded at 1 and 3 weeks of the study in the 32 anemic patients. Gastrointestinal symptoms and an unpleasant taste were reported by a majority of patients. The side effects were considered by the individuals to be mild in most instances, and only three patients considered them severe enough to warrant discontinuing therapy. In 607 patient-days of therapy with carbonyl iron, there was no evidence for hematologic, hepatic, or renal toxicity as judged by individual and mean values for WBC, platelets, bilirubin, SGOT, SGPT, alkaline phosphatase, and creatinine measured at 0, 1, and 3 weeks.

Cost. Carbonyl iron powder was purchased from GAF Corp (Linden, NJ) at a price of 2 cents per gram. For comparison, the current average price of ferrous sulfate (20% iron) is 35 cents per gram iron, based on manufacturers' listings in the 1985 *Drug Topics Red Book* for the purchase of 100 capsules or tablets The cost of the treatment regimens with carbonyl iron in this study ranged from $ 37 to $1.95; standard-dose ferrous sulfate therapy for 4 weeks would have cost, on the average, $1.78 In this comparison, we were unable to take into consideration any additional cost that would result were carbonyl iron to be marketed as a pharmaceutical

DISCUSSION

Our results suggest that carbonyl iron is safe and effective for the treatment of iron deficiency anemia, is associated with tolerable side effects, and may have a cost comparable to that of ferrous sulfate. We investigated its use as a pharmacologic agent because of studies indicating that carbonyl iron has very low toxicity when compared to standard iron therapy with ferrous salts.[5,11,18] In preliminary dosage and toxicity studies, healthy volunteers were given single doses of carbonyl iron ranging from 100 to 10,000 mg with no evidence for toxicity and with mild side effects. It is of note that the 10,000-mg dose of carbonyl iron given to four volunteers is over half the lethal dose of iron as ferrous sulfate (about 14,000 mg in a 70-kg male).[19] In five healthy volunteers (Fig 1), the increase in serum iron following a dose of carbonyl iron was less abrupt but more sustained than that from an equivalent dose of ferrous sulfate. Similar results have been obtained in studies of the pattern of absorption of the two forms of iron in rats (Huebers et al, unpublished observations), but no direct studies of the absorption of carbonyl iron in humans are available. Because of the difference in the pattern of absorption between carbonyl iron and ferrous sulfate, relative amounts of iron absorbed with the two iron preparations could not be determined from the data shown in Figs 1 and 2.

A short course of 1 to 4 weeks of carbonyl iron was used to treat patients with mild and moderate iron deficiency anemia. The daily doses of carbonyl iron (1,000 to 3,000 mg in capsules, each containing 500 to 1,000 mg) were 5 to 15 times the usual recommended dose of iron as ferrous sulfate (200 mg in tablets, each containing 65 mg),[32] yet side effects were tolerable and there was no evidence of hematologic, hepatic, or renal toxicity. In rats and guinea pigs, the acute lethal dose of carbonyl iron powder lies between an LD_0 of 10,000 mg/kg and an LD_{100} of 60,000 mg/kg.[11] If we extrapolate these data to humans, a small child of 10 kg body weight ingesting the largest amount of carbonyl iron prescribed in this study, 84 1-g capsules over 28 days, would have ingested an amount well below the LD_0. For comparison, the estimated lethal dose of ferrous iron (200 mg Fe/kg)[19] for such a child would be 37 ferrous sulfate tablets (65 mg Fe each), or a 10-day supply for standard adult therapy.

The increases in hemoglobin concentration with carbonyl iron therapy in this study are comparable to those described in previously published studies reporting response to ferrous sulfate[7,33-36] and to parenteral iron.[8,37] It has been shown that the rate of rise in hemoglobin in response to parenteral iron therapy varies inversely with the initial hemoglobin concentration.[37] Our results with carbonyl iron also show an inverse relation between the rate of hemoglobin regeneration and the initial hemoglobin concentration similar to that reported in the study with parenteral iron.[37] The continued slight mean rise in hemoglobin of .01 g/dL per day following discontinuation of carbonyl iron therapy may have occurred in response to iron that had been absorbed and stored during the period of carbonyl iron therapy, or it may have been due to dietary iron; similar results have been observed both with patients on prolonged ferrous sulfate therapy and with untreated patients responding to dietary iron.[36]

In the 14 patients who achieved serum ferritin >12 µg/L at the end of 12 weeks of observation, mean serum ferritin was 26 µg/L. This concentration is almost identical to the mean value of 25 µg/L observed in a population of women who were repeat blood donors,[38] suggesting that in these patients some iron stores may have been replaced. Further examination of these results shows that while serum ferritin was >12 µg/L in 12 of 19 (63%) patients whose initial hemoglobin was greater than 11.0 g/L, it was above this concentration in only 2 of 13 (15%) patients whose initial hemoglobin was less than 11.0 g/dL. This suggests that although in most patients with mild iron deficiency anemia (hemoglobin 11.0 to 12.0 g/dL) enough iron was absorbed during short-term carbonyl iron therapy to correct anemia and to replace some storage iron, in most patients with moderate anemia (hemoglobin 8.9 to 11.0 g/dL) all of the iron absorbed was ultimately used in erythropoiesis. However, in group VI, which received the greatest amount of carbonyl iron, the final hemoglobin concentration was in the normal range, and the serum ferritin concentration was >12 µg/L in all subjects, suggesting that even a short-term course of carbonyl iron can correct anemia and may at least partially rebuild iron stores in patients with mild iron deficiency anemia. It can be noted parenthetically that in our study, as has been previously reported,[39-41] there was a rise in serum ferritin during iron therapy, which apparently did not reflect storage iron (Fig 3). It was for this reason that we used the final serum ferritin values, obtained 56 to 77 days after completion of iron therapy, as the indicator of storage iron. It should also be pointed out that in this study we have not shown that the final hemoglobin concentration, though in the normal range, was the optimal level for the individual patients. It is possible that the hemoglobin concentration continued to rise after 12 weeks (Fig 3) and that some storage iron was used for hemoglobin production after 12 weeks. The 12-week serum ferritin cannot, therefore, be viewed as a definitive measure of storage iron achieved by carbonyl iron therapy in this study

Side effects occurred in most anemic patients given carbonyl iron in this study, predominantly diarrhea, abdominal cramps, and an unpleasant taste sensation. Although such side effects are a potentially serious drawback to the use of carbonyl iron therapeutically, it should be emphasized that most of the individuals considered them mild and tolerable. In the nonanemic volunteers who received a single dose of ferrous sulfate and a single dose of carbonyl iron that contained a 30-fold greater amount of elemental iron, there were no significant differences in overall gastrointestinal side effects between the preparations, but when abdominal cramping and diarrhea were considered separately, their incidences were significantly more frequent with carbonyl iron. Also, since giving a placebo for iron deficiency anemia is associated with a significant incidence of side effects,[42] defining the true incidence of side effects related to carbonyl iron requires a randomized double-blind trial comparing carbonyl iron, ferrous sulfate, and a placebo. Such a trial is now in progress.

Although the exact mechanism of intestinal absorption of iron is still not known, we believe the evidence from this study suggests that absorption of the doses of carbonyl iron used here proceeds in a controlled physiologic manner. Supporting observations include the following: (1) In healthy volunteers, incremental doses of carbonyl iron led to increasing increments in serum iron following the dose (Fig 1); (2) the iron-binding capacity of the serum was not exceeded even with large doses of up to 10,000 mg of carbonyl iron (Fig 1); (3) following an increase in the serum iron after a dose of carbonyl iron, there was a decline in the serum iron at 12 and 24 hours as seen with ferrous sulfate (Fig 2); and (4) in the anemic patients, intact mucosal selectivity in the absorption of carbonyl iron was suggesting by the declining percent absorption associated with increasing cumulative dose of iron and the length of treatment, as is seen with ferrous sulfate therapy.[34] Although an original observation by Volkheimer[43] described nonphysiologic "persorption" of carbonyl iron particles directly into the portal blood in dogs, the doses he gave (when adjusted for body weight) were approximately 80 times the largest dose given to healthy volunteers and 700 times the largest dose given to anemic patients in our study. Previous studies in our laboratory[44] showed "no evidence of particulate or elemental iron" on histologic and electron microscopic examination of the livers of rats fed with extremely large quantities of carbonyl iron (2.5% wt/wt of the diet) for up to 6 months. Studies in rats using radioactive carbonyl iron have also found no evidence for "persorption" (Heubers et al, unpublished observations).

In this study brief courses of 1 to 4 weeks of carbonyl iron therapy were examined to determine the extent to which anemia could be corrected and storage iron replenished with such short-term therapy. Since an earlier study with animals had shown that a single large oral dose of carbonyl iron corrected iron deficiency anemia and replaced storage iron,[19] we wished to find the largest safe daily therapeutic dose of carbonyl iron with side effects no greater than those associated with ferrous sulfate. In addition, with the 12-week observation period, the short-term therapy allowed us to estimate the amount of iron absorbed as described in Materials and Methods. The mean (±SEM) amount of carbonyl iron absorbed per day for the various treatment groups was estimated to be 12 ± 3 to 47 ± 9 mg (Table 3). These amounts compare favorably with the amount of orally administered iron that the marrow can use for erythropoiesis in mild and moderate iron deficiency anemia, approximately 10 to 20 mg per day,[45,46] and coincide with the finding that in some of our patients, iron in excess of what was neeeded for erythropoiesis was absorbed and may have been used to replenish storage iron.

In summary, our results provide evidence that carbonyl iron is a safe, effective, well-tolerated, and inexpensive therapy for iron deficiency anemia. Most important, carbonyl iron may have an advantage when compared to the ferrous salts now in use by decreasing accidental iron poisoning in children. Although there is no direct experience with use of carbonyl iron in children, experience in normal volunteers[5] and in animals[11,18] suggests that the risk of toxicity and poisoning in children would be greatly reduced when compared to ferrous salts. Patients with mild anemia may correct anemia and rebuild iron stores with even a short course of carbonyl iron, but the optimal dose and duration of therapy for more severe anemia remain to be determined.

High Frequency of *N-ras* Activation in Acute Myelogenous Leukemia

By Samuel W. Needleman, Matthias H. Kraus, Shiv K. Srivastava, Paul H. Levine, and Stuart A. Aaronson

Using the NIH/3T3 cell transfection assay, activated cellular oncogenes have been detected in around 10% to 20% of human tumors. From a series of DNA preparations from tissues infiltrated with acute myelogenous leukemia (AML), 50% (3/6) caused transformation of NIH/3T3 cells. Thus AML appears to be the human tumor with the highest frequency of oncogenes detected by DNA transfection. In each case the oncogene involved was *N-ras*, a member of the *ras* gene family. Biologic and clinical parameters of AML patients with and without *N-ras* oncogenes in their tumors are discussed.

EVIDENCE ARISING FROM several different approaches has implicated a small number of cellular genes or proto-oncogenes as frequent targets for genetic alterations that can lead human cells along the pathway to malignancy. These cellular genes were initially identified as the transduced cellular "*onc*" genes of acute transforming retroviruses.[1,2] More recently, it has been found that some of the very same cellular genes may be activated as oncogenes in human tumors completely independent of retrovirus involvement.[3-5]

One important approach to the detection of human transforming genes has involved DNA transfection. A wide variety of human tumors contain DNA sequences capable of inducing morphologic transformation upon transfection of NIH/3T3 cells, a continuous mouse embryo cell line.[6-11] The vast majority of oncogenes detected in this manner have been found to be related to a small proto-oncogene family, *ras*. Recent studies have also implicated other proto-oncogenes in human malignancies. DNA rearrangements such as translocation and gene amplification involving human proto-oncogenes have been associated with specific forms of cancer.[12-16]

Human acute myelogenous leukemia (AML) is a highly malignant hematologic neoplasm. There have been a few reports of *ras* oncogenes in neoplastic tissues or cultures derived from AML patients, as well as a recent study demonstrating amplification of the proto-oncogene *c-myb* in one AML cell line.[11,17-19] This present study of six patients with AML was undertaken to examine further the frequency of oncogene activation in this disease, as well as to characterize what clinical parameters, if any, might be associated with oncogene activation.

MATERIALS AND METHODS

DNA transfection. Pretreatment marrow aspirates or autopsy materials were selected if they were heavily (>75%) infiltrated with acute nonlymphocytic leukemia cells as judged by a pathologist. Specimens selected for study were frozen promptly to prevent DNA degradation, and tumors were homogenized in liquid nitrogen, lysed in .5% sodium dodecyl sulfate (SDS) containing 10 mmol/L Tris, 2 mmol/L EDTA, and 150 mmol/L NaCl and treated overnight with proteinase K (.2 mg/mL at 37°C). Proteins were extracted with phenol, then with a mixture of phenol, chloroform, and isoamyl alcohol (25:24:1), and then with chloroform and isoamyl alcohol (24:1). DNA was precipitated with ethanol, dried, and suspended in 1 mmol/L Tris and .2 mmol/L EDTA.

The DNA transfection assay was performed essentially as described.[20] Briefly, NIH/3T3 cells were plated in 10-cm petri dishes at 1.3×10^5 cells per plate 20 hours before transfection. DNA (30 μg) was suspended in .25 mol/L $CaCl_2$ and precipitated by addition to an equal volume of 50 mmol/L HEPES, 280 mmol/L NaCl, and 1.5 mmol/L NaH_2PO_4 during gentle nitrogen bubbling. After 30 to 60 minutes, precipitates were resuspended and added to the NIH/3T3 cell monolayer. Precipitates were removed 20 hours later. Culture medium was changed twice weekly, and focus formation was scored at 14 to 21 days. Genomic DNA from the T24 human bladder carcinoma cell line was used as a positive control. T24 DNA yielded 5 to 15 focus-forming units per plate.

Southern blot analysis. DNAs (15 μg lane) were electrophoresed at 30 V in 1% agarose and transferred to nitrocellulose by the method of Southern.[21] Molecular probes were nick-translated with $\alpha^{32}P$ dCTP, denatured, and hybridized overnight at 42°C in the presence of 50% formamide, 750 mmol/L NaCl, 75 mmol/L Na citrate 1X Denhardt's solution, 20 mmol/L phosphate buffer, and 100 μg/mL sheared, denatured salmon sperm DNA. The filters were washed three times with 300 mmol/L NaCl, 30 mmol/L Na citrate, and .1% SDS at room temperature and then with 15 mmol/L NaCl, 1.5 mmol/L Na citrate, and .1% SDS twice at 50°C. After air drying, the filters were exposed two to six hours at −80°C on an intensifying screen and developed in a Kodak RP X-O-Mat processor. DNA probes of human origin included *N-ras*, *K-ras*, *H-ras*, *c-myc*, *c-myb*, and *N-myc*.

Immunoprecipitation of the ras *gene product.* Two days following plating a density of 3×10^6 cell cultures were methionine-starved for 30 minutes and labeled with .3 mCi L-^{35}S-methionine/mL for three hours. After washing with phosphate-buffered saline (PBS), the cells were lysed in 1% Triton-X-100, .1% SDS, .5% sodium deoxycholate, .1 mol/L NaCl, 10 mmol/L phosphate buffer (pH 7.4) containing 1.5 mmol/L phenylmethylsulfonyl fluoride (PMSF), and 100 kallikrein inactivator units of aprotinine/mL. After centrifugation at 30,000 g for 15 minutes, 2×10^7 trichloroacetic-acid precipitable counts of the cleared lysates were incubated with anti-*ras* monoclonal antibody Y13-259[22] at 4°C for 45 minutes. Bound p21 was precipitated with protein A sepharose coated with goat antirat IgG, washed three times, and boiled in sample buffer containing 2-mercaptoethanol. Samples were electrophoresed at 250 V for three hours along with ^{14}C-labeled protein standards on a 12.5% bis-acrylamide slab gel. Following fixation, fluorography with Enhance, and rehydration, the slab gel was dried and exposed overnight on an image-intensifying screen at −80°C.

RESULTS

High-frequency activation of N-ras *oncogenes in primary AML.* Table 1 provides information on six patients with AML included in our study. DNA extracted from tumor tissues was assayed in the NIH/3T3 transfection assay. As shown, affected tissues of three of the patients scored as positive. In each case, the transforming activity persisted in a second cycle of transfection. The great majority of activated oncogenes associated with human malignancies and detected in the NIH/3T3 transfection assay are members of the *ras* gene family. *H-* and *K-ras* were initially detected as the transduced *onc* genes of transforming retroviruses,[23] while *N-ras* was initially detected as the oncogene of a human neuroblastoma cell line.[24] Thus we probed first-cycle transfectants with radiolabeled DNA fragments derived from human *H-*, *K-*, and *N-ras*, respectively. Neither *H-* nor *K-ras* probes detected new, hybridizable DNA fragments (data not shown). However, each of the transfectant DNAs contained new DNA fragments detectable under stringent hybridization conditions with the *N-ras* probe (Fig 1). Similar results were obtained with second-cycle transfectants, indicating the segregation of human *N-ras* sequences with the transformed phenotype of the cells. Differences in the sizes of *Eco*RI-digested *N-ras* fragments imply DNA rearrangements outside the region that is required for *N-ras*-transforming function during the transfection and/or integration process.

Recent studies have documented that activating lesions at codon 12 or 61 in the *ras* coding sequence and the consequent amino acid substitution at either of these positions can alter the electrophoretic mobility of the transforming protein. These alterations induce characteristic retarding or accelerating effects of p21 migration.[25,26] Thus we examined transfectants containing *N-ras* oncogenes derived from the three positive AML patients by immunoprecipitation analysis for their pattern of p21 electrophoretic mobility using broadly cross-reactive anti-p21 monoclonal antibody Y13-259. As shown in Fig 2, representative transfectants of each positive AML exhibited abnormal p21 species; when compared with normal NIH/3T3 cells, the level of p21 expression was consistently elevated in all transfectants analyzed. The increased expression of p21 in AML transfectants is attributed to the presence of the added human *N-ras* oncogene because DNA hybridization experiments established that the transfectants contained only human *N-ras* and not human *H-ras* or *K-ras* oncogenes or amplified copies of any mouse *ras* genes. However, direct identification of human *N-ras* encoded p21 proteins is not possible as yet due to the unavailability of *N-ras*-specific antibodies. Each of the three *N-ras* oncogene products demonstrated a similar migration, suggesting that a similar mutational event might be responsible for the activation of *N-ras* oncogenes in each of these cases.[26]

Table 1. DNA Transfection Analysis of Six Cases of Acute Myelogenous Leukemia

Patient	Age	Sex	Survival (months)	Tissue	Transforming Activity (foci/plate) First Cycle	Transforming Activity (foci/plate) Second Cycle
1	45	F	30+	Marrow	2/8	45/8

Control NIH/3T3 (lane 1) and NIH/3T3 transfectants derived from DNAs of patients 1, 2, and 3 (lanes 2, 3, and 4) were compared with transfectants of T24 bladder carcinoma containing a position 12-mutated** ***H-ras*** **(lane 5) and of SW1271 lung carcinoma containing a position 61-mutated** ***N-ras*** **(lane 6). After immunoprecipitation with monoclonal antibody Y13-259, p21 electrophoretic mobilities were compared by SDS 12.5% polyacrylamide gel electrophoresis.**

Somatic activation of N-ras *in an AML patient.* The family history of patient 1 indicates a high incidence of hematopoietic abnormalities, including paroxysmal nocturnal hemoglobinuria (PNH), neutropenia, acute leukemia, and Hodgkin's disease. It is conceivable that families with site-specific tumor aggregation[27] inherit a propensity for the development of the tumor by vertical passage of an altered or activated oncogene. This prompted us to investigate whether the DNA from this patient's normal tissue might contain an activated cellular oncogene. DNA extracted from apparently normal skin scored repeatedly negative in the NIH/3T3 transfection assay, with a total of 16 plates analyzed under conditions where the activated *N-ras* gene of this patient's leukemia tissue was readily detectable (Table 1). These findings suggest that *N-ras* activation in this patient occurred as a somatic event in agreement with the results of similar studies of other tumors.[28-30]

Hybridization analysis of human AML DNAs for aberrations affecting other human proto-oncogenes. Recent studies have identified rearranged *c-myc* in Burkitt's lymphoma as well as amplification of *c-myc*-related genes in a number of other human malignancies.[12,13,15,18,31] In addition, *c-myb* has been shown to be amplified in one AML cell line.[19] Thus we surveyed DNAs of our series of primary AMLs for evidence of gene rearrangements or gene amplification affecting either of these proto-oncogenes. There was no detectable amplification or gross DNA rearrangement with respect to the indicated restriction enzyme involving either *myb* (Fig 3) or *myc* (data not shown) in any of the samples analyzed, indicating that such alterations are not commonly detectable in AML. Moreover, analysis of *Eco*RI- or *Bam*HI-digested genomic DNA failed to reveal DNA rearrangement or gene amplification of *H-ras*, *K-ras*, *N-ras*, or *N-myc* (data not shown).

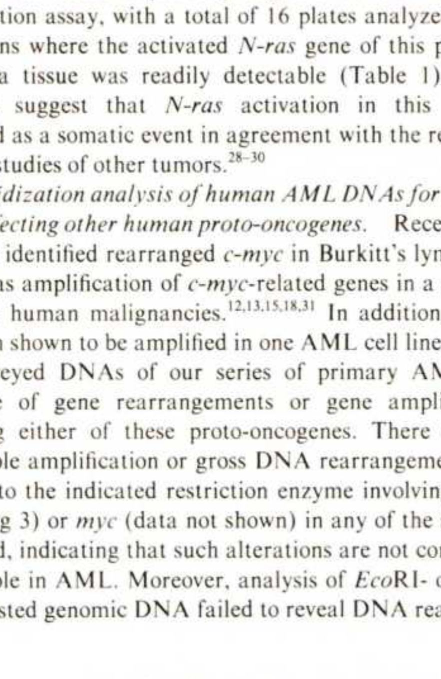

Fig 3. Analysis of human AML DNAs for aberrations affecting other proto-oncogenes. DNA samples (15 μg) from seven AML patients (lanes 1 through 7) and human placenta (lane 8) were digested with *Hind*III and hybridized to the 2.6-kb and 1-kb *Eco*RI fragments of human *c-myb*.[40]

DISCUSSION

Our observations that 3 of 6 tumors contained an activated *N-ras* oncogene suggest that approximately 50% of the neoplastic tissues from patients with AML will score as positive in the NIH/3T3 DNA transfection assay. In considering our cases in concert with the five cases of AML examined in other studies,[11,17,18] a total of 6 of 11 were positive. There have only been a few studies of the frequency of *ras* oncogene activation in a large series of tumors of the same types. In breast and urothelial tumors, the frequency of *ras* oncogenes detected by DNA transfection was <5% and around 7.5%, respectively.[29,30] The combined results of several studies have indicated that lung and colon carcinomas exhibit *ras* oncogenes detected by analogous approaches in around 10% to 30% of primary tumors or tumor cell lines.[10,25] Thus AML appears to exhibit the highest frequency of *ras* oncogene activation of any human tumor so far studied.

It is possible that oncogene activation detectable in the NIH/3T3 transfection assay reflects some biologic property intrinsic to the tumor subtype in question. NIH/3T3 cells lose density-dependent growth inhibition and become tumorigenic in nude mice after transfection with activated *ras* genes. Thus it is conceivable that tumors expressing *ras* oncogenes might be relatively more aggressive with respect to tissue invasiveness and/or metastatic potential. In our present series of AMLs, such clinical parameters as leukocyte count at presentation, degree of organ infiltration, response to therapy, and survival did not seem to be significantly correlated with the presence or absence of detectable *N-ras* oncogenes. However, further studies of *N-ras* activation in AML are needed to validate these findings and explore further whether detection of this marker is associated with any subgroup of patients with distinctive biologic and/or clinical behavior of their disease.

Previous studies have demonstrated that in a few tumors where normal tissues from the same patient were available, *ras* oncogenes were activated by point mutations as somatic events detectable only in the tumor.[28-30] In our present survey of human AMLs, we were able to analyze DNA of normal cells from one patient whose tumor was positive for an *N-ras* oncogene. This patient's family history indicated a high incidence of hematopoietic abnormalities, including PNH, neutropenia, acute leukemia, and Hodgkin's disease. The absence of oncogenes detectable by DNA transfection in normal tissues of this patient suggests the somatic activation of an *N-ras* oncogene in this tumor. While genetic transmission of an *N-ras* oncogene cannot be implicated in the high familial incidence of hematopoietic abnormalities, its selection within the tumor implies that it was likely involved in this patient's tumor development.

The mobilities of *ras* p21 proteins altered by the most common activating lesions at codon 12 or 61 are often altered in ways that readily discriminate them.[26] Our present findings demonstrated that the mobilities of p21s encoded by each of the *N-ras* oncogenes of our AML patients analyzed were similar, but intermediate in mobility compared to those of typical p21s containing position 12 or 61 mutations. These findings indicate that these oncogenes may possess a common mutation, whose effect on p21 mobility doesn't allow ready classification. The precise mechanisms by which these oncogenes are activated awaits their molecular cloning and sequence analysis. In a report published after submission of our study, Bos et al[32] also detected *N-ras* oncogenes at high frequency in AML. Moreover, these investigators presented evidence that point mutation at codon 13, rather than at one of the common sites for activation at position 12 or 61, is responsible for the acquisition of transforming properties by *N-ras* oncogenes in their cases of AMLs. It will be of interest to determine whether position 13 mutations account for any of the activating lesions in our present studies of *N-ras* as agents of AML patients.

Chromosomal aberrations such as translocations, inversions, and deletions occur in the majority of AMLs.[33] Specific translocations have been implicated in the activation of proto-oncogenes in Burkitt's lymphoma[12] and chronic myelogenous leukemia.[14] Although it was not possible to perform cytogenetic analysis of our present cases, the karyologic anomalies observed in AML involve chromosome 1 where the *N-ras* proto-oncogene resides in less than .5% of cases.[34] In fact, in those cases where chromosome 1 anomalies are observed in AML, the break point is more often at the long arm of chromosome 1,[34,35] while the *N-ras* site is on the short arm, at 1p11 to 1p21.[34] Thus the observation of a high frequency of *N-ras* activation in AML coupled with the very rare observation of chromosomal anomalies in the vicinity of this gene strongly suggests that a specific primary karyologic change is not involved in *N-ras* activation.

Myc and *myb* oncogenes of acute transforming retroviruses commonly induce myeloid leukemias.[1,2] *Ras* oncogenes have been shown to induce alterations in the growth and differentiation of cells within the myeloid lineage, in some cases associated with the acquisition of malignant properties.[36,37] In view of these findings as well as reports of amplified *myb*[19] and *myc*[38,39] DNA sequences, respectively, in two different myeloid leukemia cell lines, we investigated seven primary AMLs for evidence of gene amplification or gross DNA rearrangement involving *myc* and related *N-myc*, *myb* and the three *ras* oncogenes. None was detected, implying that such alterations are not commonly associated with this tumor. Continued search for specific aberrations affecting the small set of cellular genes that are known to give rise to oncogenes may help to define other genes that contribute to the pathogenesis of this highly malignant tumor.

Loss of the Largest von Willebrand Factor Multimers From the Plasma of Patients With Congenital Cardiac Defects

By Joan C. Gill, Allen D. Wilson, Janet Endres-Brooks, and Robert R. Montgomery

We identified a consecutive series of 12 children with noncyanotic congenital cardiac lesions with loss of the largest plasma von Willebrand factor (vWF) multimers determined by SDS-agarose electrophoresis. Seven had previous histories of mucocutaneous hemorrhage; ten had a prolonged bleeding time. Analysis of the factor VIII molecular complex revealed that six patients had reduced vWF measured both immunologically (vW:Ag) and by ristocetin cofactor assay (vW:rist). All had normal or borderline normal factor VIII procoagulant (F VIII) concentrations. Three children had prolonged partial thromboplastin times due to concurrent factor XII deficiency; none had laboratory evidence of intravascular coagulation. Five of the children were restudied after surgical correction of their cardiac lesions. Four had normalization of vWF multimers; the fifth, whose vWF was abnormal postoperatively, had a residual pressure gradient across a previous pulmonary artery banding site. Multimeric abnormalities were not found in the parents of three patients. Thus some patients with noncyanotic congenital heart disease may have an acquired abnormality of vWF that is normalized with correction of the abnormal hemodynamic state.

© 1986 by Grune & Stratton, Inc.

THE PLASMA FACTOR VIII molecular complex is composed of two proteins: factor VIII (F VIII), the procoagulant protein that functions as a cofactor in factor IXa activation of factor X in blood clotting; and von Willebrand factor (vWF), the large multimeric protein that supports platelet adhesion.[1,2] Both proteins can be measured immunologically and functionally; thus both qualitative and quantitative abnormalities of vWF are possible and have been described.[1-3] Patients with inherited von Willebrand disease (vWD) of type II have qualitative defects of vWF; these defects are manifested by mild to moderate mucous membrane and cutaneous hemorrhages, prolonged bleeding times, decreased vWF-ristocetin cofactor activity (vW:rist), and absence of the large vWF multimers demonstrated by sodium dodecyl sulfate (SDS)–agarose electrophoresis of plasma.[2,3] Acquired defects of vWF have been reported in patients with disseminated intravascular coagulation (DIC),[4,5] the episodic form of hemolytic uremic syndrome,[6] acute myocardial infarction,[7] and myeloproliferative syndrome.[8]

We recently had the opportunity to study nine patients with ventricular septal defect (VSD), one with atrial septal defect (ASD), and two with aortic stenosis. Each patient was referred for evaluation of hemorrhagic symptoms or a long bleeding time. All 12 patients had apparent acquired absence of the largest vWF multimers by SDS-agarose electrophoresis.

MATERIALS AND METHODS

Patients. The 12 consecutive patients were referred for either evaluation of hemorrhagic symptoms or abnormal preoperative hemostatic screening tests. Laboratory evaluation was performed at Milwaukee Children's Hospital Clinical Laboratory and the Hemostasis Reference Laboratory of the Blood Center of Southeastern Wisconsin, Milwaukee. Careful histories and physical examinations were conducted for all patients.

Collection of blood samples. Plasma was obtained from venous blood sampled by a double-syringe technique and anticoagulated with sodium citrate (3.2%). Platelet-rich plasma was obtained by centrifugation of anticoagulated whole blood at 1,600 g for five minutes and platelet-poor plasma by centrifugation at 4,800 g for 20 minutes in a refrigerated centrifuge.

Standard coagulation assays. Bleeding times were calculated with the Simplate device (General Diagnostics, Morris Plains, NJ) according to the manufacturer's suggestions. Prothrombin (PT) and partial thromboplastin (PTT) times were determined by recalcification assays on an MLA Electra-700 (Dade, Mount Vernon, NY). Platelet counts were performed on an ELT-8DS (Ortho, Boston) and confirmed by visualizaton of Wrights-stained peripheral blood smears by light microscopy. Fibrinogen assays were performed on a fibrometer utilizing Data-Fi fibrinogen reagents (Dade, Miami) and fibrin(ogen) degradation products by the Thrombo-Wellco Test (Burroughs-Wellcome, Research Triangle Park, NC).

Studies of the factor VIII molecular complex. Factor VIII procoagulant activity (F VIII:C) was determined by a one-stage method using F VIII–deficient plasma as a substrate.[9] Quantitative measurement of vWF (vW:Ag) was performed using a rocket immunoelectrophoretic technique in .9% agarose with rabbit antihuman vWF.[10] Ristocetin cofactor activity of vWF (vW:rist) was determined using formalin-fixed human platelets.[11] Multimeric analysis of vWF was determined by electrophoresis of plasma in .65% Seakem HGT-(P) agarose gels (FMC Corp, Rockland, Me) in the presence of .1% SDS and visualized by radiolabeled rabbit antihuman vWF and autoradiography as previously described.[12] The reference standard for factor VIII and vWF assays was pooled plasma from 50 normal donors (stored at −80°C).

RESULTS

During the period from June 1982 to December 1984, nine patients with ventricular septal defect (VSD), one with atrial septal defect (ASD), and two with aortic stenosis were referred for evaluation of hemorrhagic symptoms or an abnormal preoperative hemostatic screening test. Seven of the 12 patients had a history of mucocutaneous bleeding (Table 1). Of these, four patients (3, 6, 8, and 11) had lifelong histories of bleeding; the remaining three were studied at the time of presentation of the symtoms listed in Table 1.

¶Gastrointestinal hemorrhage.

Evaluation of the factor VIII molecular complex (Table 1) revealed that all but two of the children had normal concentrations of plasma F VIII:C (50 to 150 U/dL); patients 6 and 12 had borderline abnormal values of 49 and 47 U/dL, respectively. However, analysis of vWF showed that six patients had reduced (<50 U/dL) concentrations of vWF measured both immunologically (vW:Ag) and by ristocetin cofactor assay (vW:rist). Patients 2, 4, 6, 9, 10, 11, and 12 had lower vW:rist values compared to vW:Ag, but there was good agreement between the immunologic and ristocetin cofactor assays in the remaining five patients. All 12 patients had loss of the highest mol wt subunits of vWF demonstrated by SDS-agarose electrophoresis (Fig 1). Low-dose (.6 mg/mL) ristocetin-induced platelet aggregation was absent in two patients (4 and 8); others were not studied. Five patients were studied on two or three occasions over a period of 1 to 18 months prior to surgery. Each patient had repeatedly abnormal vWF multimeric analyses.

The routine coagulation studies are summarized in Table 2. Ten of the 12 patients had a prolonged bleeding time (>10 minutes); in no case was the long bleeding time explained by thrombocytopenia since all twelve patients had a normal or slightly elevated platelet count. With the exception of patient 7, who had a borderline low fibrinogen value, none of the patients had evidence of intravascular consumption of coagulation factors; none had an abnormal PT or thrombin time or elevation of fibrin(ogen) degradation products. Three patients (10, 11, and 12) had a prolonged PTT explained by a decreased factor XII level (14, 44, and 41 U/dL, respectively).

To determine whether the abnormal vWF multimeric pattern was present in association with the cardiac anomaly, five patients were studied after surgical correction of the cardiac defect. Four patients (4, 6, 8, and 9) who had loss of the largest vWF multimers preoperatively had normalization of the multimeric pattern following repair (Fig 2). Although patients 4, 8, and 9 had normal vWF as measured by all methods including vWF multimers and patient 6 had only a mild decrease in both vW:Ag and vW:rist (43 and 45 U/dL, respectively), all four patients still have markedly prolonged bleeding times. Patient 4 had platelet aggregation studies both preoperatively and postoperatively; her platelets aggregated normally when the agonists epinephrine, collagen, arachidonate, and ADP were added to her platelet-rich plasma. The fifth child (patient 5) was studied initially 8 years after repair of her VSD and had abnormal vWF multimers; she also had a residual pressure gradient across a previous pulmonary artery banding site.

Further evidence for the acquired nature of the vWF anomaly was found by family studies. None of the parents available for study had evidence of vWF multimeric abnormalities. Two parents did have mildly decreased concentrations of vW:Ag (36 and 43 U/dL respectively).

To determine if these children were different from others with VSD or ASD who underwent catheterization and surgical repair during the same time period, cardiac catheterization findings were evaluated. Eight of nine patients with VSD had a sealed foramen ovale, and all had high-end

*This PTT was outside the normal range established at the time of this study.

diastolic pulmonary artery pressure. Since other patients with cardiac defects may also present these features, it is unknown whether this finding is the only explanation for the vWF abnormalities.

One patient (6) was studied before and after infusion of cryoprecipitate. After administration of 1 donor unit/5 kg body weight, his vW:Ag rose from 37 to 60 U/dL and his vW:rist from 22 to 65 U/dL, and his abnormal multimeric pattern was almost completely corrected (Fig 2). His bleeding time, however, only partially corrected from a preinfusion value of 17 minutes to 12 minutes postinfusion. None of the patients had excessive intraoperative or postoperative bleeding, but all received large amounts of fresh frozen plasma and platelet concentrates during the postoperative period as part of the routine surgical management of open-heart cases. No increased use of such products was noted.

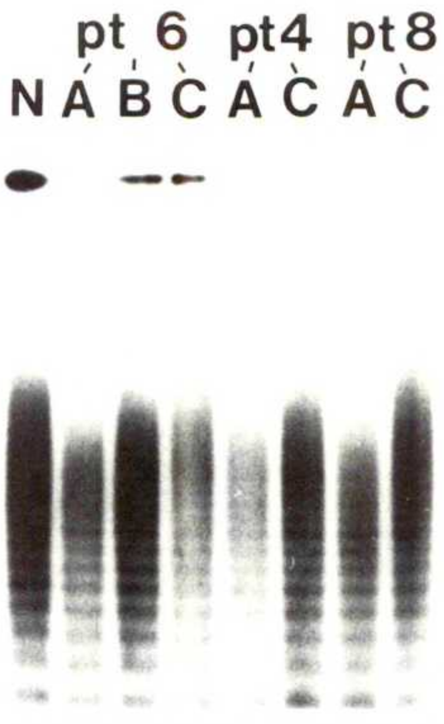

Fig 2. Normalization of vWF multimers in patients with congenital cardiac defects following surgical repair and following infusion of cryoprecipitate. For each patient, lane A contains the preoperative sample and lane C the postoperative sample. Lane B is the postcryoprecipitate infusion sample from patient 6. Note normalization of the vWF multimer pattern in lanes B and C.

DISCUSSION

Von Willebrand factor is a plasma protein composed of large multimers of .4 × 10^6 to 20 × 10^6 daltons mol wt.[3] Both inherited and acquired abnormalities of the protein have been described; patients with a vWF hypoproteinemia (decreased amounts of normal vWF) have von Willebrand disease of type I, and those with a dysproteinemia (abnormal vWF with normal or reduced amount of protein) have type II. Type II vWD is characterized by the absence of the large vWF multimers when analyzed by SDS-agarose electrophoresis. The absence of these hemostatically important multimers in type II vWD results in defective platelet adhesion and a clinically significant bleeding disorder.[1-3]

Acquired type II–like vWF abnormalities have been described in patients with episodic hemolytic uremic syndrome,[6] DIC,[4,5] myeloproliferative syndrome,[8] and acute myocardial infarction,[7] and we have seen this in one case of acquired type II vWD (Scott and Montgomery, unpublished observation). These patients exhibit an absence of the largest plasma vWF multimers and a discrepancy between vWF measurements by antigenic and functional assays. Our 12 patients with congenital cardiac defects also appear to have a form of acquired vWD; they have loss of the largest vWF multimers, long bleeding times, histories of mild hemorrhagic episodes, and, in one patient studied, a prolonged bleeding time that was partially corrected by the administration of cryoprecipitate. It is uncertain if all symptoms are related to the vWF defect, however, since four patients have residual hemostatic abnormalities (prolonged bleeding times) even though their vWF multimers have become normal following surgical repair of the cardiac defect. The acquired nature of the phenomenon is demonstrated by the correction of the vWF defect with surgical correction of the cardiac defect in four of the patients studied both preoperatively and postoperatively and the lack of the abnormality in parents of the affected patients. The one patient with persistence of the abnormality after correction of her VSD had an abnormal pressure gradient across a previous pulmonary artery banding site; the vWF abnormality might be explained by persistence of an abnormal hemodynamic state in this patient

The mechanism of loss of the largest vWF multimers associated with these congenital cardiac defects is unclear. Review of cardiac catheterization data in the 12 patients failed to reveal a specific characteristic that was different from those found in other children with similar cardiac lesions, with the exception that all but one of the patients with VSD had a sealed foramen ovale. Perhaps the abnormal hemodynamic flow is associated with activation of platelets or endothelial cells with resultant adsorption of the largest vWF multimers from the plasma. If adsorption of vWF to platelets is responsible for its absence from plasma, one might expect that the platelets would be agglutinated by low-dose ristocetin as is seen in type IIB vWD;[3] this was not present in the two patients tested (patients 4 and 8), although the multimeric pattern on electrophoresis in SDS-agarose is more reminiscent of type IIB vWD than of type IIA, in which all of the high–mol wt multimers are absent, rather than only the largest as seen in these patients. Another possible mechanism for the phenomenon is cleavage of the vWF multimers into smaller forms by proteolytic enzymes (possibly by plasmin[13–15] and/or the calcium-activated protease[16] similar to that described in patients with DIC[4,5]. However, there was no evidence of DIC in these patients; all had a normal PT, thrombin time, and platelet count and, in the eight studied (patients 1, 3, 4, 6, 7, 8, 10, and 11), normal concentrations of fibrinogen with lack of fibrin(ogen) degradation products. The three patients with prolonged PTTs had concurrent factor XII deficiency; none has as yet undergone surgical correction of their cardiac lesion. An association of factor XII deficiency with vWD has been reported previously;[17,18] the significance in these patients is unknown

The variety of hemostatic defects associated with congenital cardiac lesions manifested by thrombocytopenia, platelet dysfunction, and deficiency of clotting factors because of decreased synthesis, fibrinolysis, and DIC appears to be directly related to the hypoxia and hyperviscosity associated with cyanotic congenital heart disease.[19] However, as described here, in 7 of 12 children with noncyanotic cardiac lesions, clinically significant bleeding histories were found. All 12 had an associated alteration in von Willebrand factor multimers. However, it is not clear that the von Willebrand factor abnormality contributed to the bleeding histories or prolonged bleeding times since the bleeding times were not corrected with normalization of vWF following corrective cardiac surgery. Further studies to elucidate the mechanism of this phenomenon and to determine its prevalence and clinical significance in VSD and other cardiac lesions are ongoing in our laboratory.

The Sensitivity to Cytosine Arabinoside of the Blast Progenitors of Acute Myeloblastic Leukemia

By Nobuo Nara, J.E. Curtis, J.S. Senn, D.L. Tritchler, and E.A. McCulloch

Two culture methods are available for the study of the blast cells of acute myeloblastic leukemia (AML). One is an assay for clonogenic precursors; it depends on their ability to form blast colonies in culture in the presence of methylcellulose and suitable growth factors. The other assesses the growth of blast cells in suspension culture, where growth is measured by increasing numbers of clonogenic cells. We have compared the two methods as assays for the cytotoxic effects of the chemotherapeutic drug cytosine arabinoside (Ara-C). Marked patient-to-patient variation was found using either method; however, the slopes of the dose-response curves were usually greater when cells were exposed to drug in suspension rather than in methylcellulose. Control experiments showed that the difference could not be explained by drug carry-over from the suspension cultures to the methylcellulose plates when clonogenic cells in the suspensions were assessed. Further, the survival curves for Adriamycin were very similar, regardless of which assay was used. No correlation was found between D_{10} Ara-C values measured in suspension or in methylcellulose. However, a significant association with outcome was found between D_{10} Ara-C in suspension and response to treatment with a regimen in which Ara-C was the only chemotherapeutic agent used. No such association was detected when the D_{10} values obtained with the clonogenic assay were compared with outcome for the same group of 15 patients. Finally, a feasibility experiment was performed in which blast cells were exposed to Ara-C repeatedly during exponential growth over 238 days. A dose-related inhibition of growth was observed; no evidence was seen of emerging drug-resistant cells. Nor did the morphology of the cells change as a result of drug exposure. We conclude that drug sensitivities of AML blast cells in culture are dependent on measurement methods, even when techniques affecting cell proliferation are compared. Measurements of drug sensitivity in culture may best be interpreted when the bases of the assay systems are understood.

THE RESPONSE TO chemotherapy provides striking evidence of heterogeneity among patients with acute myeloblastic leukemia (AML). Some die before adequate treatment can be delivered Many, but not all, treated patients enter remission. Of these, most relapse within a year, and only a few survive for 5 years.[1-3] It is a research goal to understand the basis of this heterogeneity. We have approached the problem by seeking associations between outcome following chemotherapy and various attributes of patients, treatment regimens, or leukemic cells. For these last, cell culture methods have proved useful in the characterization.

We now employ two techniques for the culture of blasts. The first is a clonogenic assay: A small proportion of the blast population will form colonies in cultures made viscid by methylcellulose, provided a suitable source of growth factors is included.[4,5] In the second method, blast progenitors multiply exponentially in suspension culture; the requirements for growth are a cell density of 10^6 cells/mL and the same source of growth factors used in the clonogenic assay.[6]

Both methods are consistent with a model of the blast population that postulates its maintenance by blast stem cells; these may renew themselves or enter a determination-like process yielding cells capable of only terminal divisions.[7] In the clonogenic assay, colony formation reflects primarily these terminal divisions; self-renewal can be demonstrated only by replating colonies, either singly or as pools.[8] This secondary plating efficiency (PE_2), though variable from patient to patient, is always low, indicating that few of the divisions required for colony formation lead to new clonogenic cells. On the other hand, the exponential increase in blast progenitors seen in suspension cultures may be considered to reflect self-renewal; the presence of end cells is deduced from the observation that the doubling time in culture of blast progenitors growing in suspension is longer than their generation time. The difference in the extent of self-renewal seen in the two assays may reflect inhibitory effects of methylcellulose.[6]

Blast heterogeneity is evident with either culture method. For the clonogenic assay, a significant association has been found repeatedly between successful remission induction and low plating efficiencies when blast colonies are subcultured (PE_2).[8-10] In contrast, no such link has emerged between response and the sensitivity of colony formation to the chemotherapeutic drugs used in treatment. Others have obtained similar results, particularly in settings where cytosine arabinoside (Ara-C) was the only chemotherapeutic agent used.[11,12] It seemed possible that the effect of drug on self-renewal might be more important than its capacity to reduce colony formation. This view was strengthened with the finding that PE_2 was reduced compared to controls when colonies surviving after exposure to Ara-C were replated,[9,13] while no such change was found after exposure to Adriamycin.

These considerations led us to compare the Ara-C sensitivity of blasts when determined by each method. We found marked patient-to-patient variation regardless of technique; however, Ara-C was usually more effective against blasts in suspension than in methylcellulose. Further, the slopes of the simple negative exponential survival curves (D_{10}, dose required to reduce survival to 10% of control) obtained by

each technique were not correlated, and for a small number of patients, a significant association was found between D_{10} Ara-C in suspension and successful remission induction. We also demonstrated the feasibility of exposing blast populations to drug repeatedly during prolonged exponential growth.

MATERIALS AND METHODS

Patients and treatment Heparinized peripheral blood was obtained from 21 patients with AML at the time of diagnosis or at relapse, with informed consent, as prescribed by a protocol approved by the Human Experimentation Committee of the University of Toronto. The diagnosis was based on cell morphology according to the FAB classification[14] and the clinical criteria used at the Ontario Cancer Institute in clinical trials of AML.[15] Table 1 contains the clinical characteristics, treatment, and responses to treatment of the patient group. The patients seen at diagnosis received a high-dose Ara-C protocol [16] The protocol consists of Ara-C 3 g/m^2 of body surface area (BSA) twice daily for six days (reducing to 2 g/m^2 BSA in patients $\geq$ 60 years) and prednisone 40 mg/m^2 BSA daily for six days for remission induction. One patient (No 6) refused treatment. Patient 5 had a previous neoplasm (carcinoma of lung) These two patients were excluded from the assessment of the reponse to therapy The patients seen at relapse were treated with a combination of chemotherapeutic drugs.

Patients were considered to have responses if they had achieved either a complete remission (CR) or a partial remission (PR).[15] The criteria for complete remission included a marrow of approximately normal cellularity with <5% blasts and <5% promyelocytes, normal number of megakaryocytes, and evidence of regenerating granulopoiesis and erythropoiesis. Normal peripheral blood counts and no evidence of clinical disease elsewhere were also required. A partial remission required a marrow of normal or moderately increased cellularity with >10% of blasts and promyelocytes but <25% blasts present Patients were followed by examinations of the peripheral blood; in all instances, the blast population was eliminated. Early (14-day) marrow aspirations were not done routinely since, in our hands, this procedure has not proved useful clinically. Bone marrow was aspirated to assess response to treatment when normal leukocytes or blast cells began to appear in the peripheral blood. This usually occurred 4 to 5 weeks after treatment was started

Blast colony assay. Primary colony formation was obtained as previously reported,[4,5] except that supernatants from cultures of the continuous line of bladder cancer cells, HTB9, obtained from the American-type culture collection, were used rather than media conditioned by leukocytes in the presence of phytohemagglutinin (PHA-LCM).[17] Suspensions containing 4 × 10^5 T cell–depleted mononuclear cells from peripheral blood suspended in 1 mL of α-MEM supplemented with 20% fetal calf serum (FCS), 10% HTB9-conditioned medium, and .8% methylcellulose were cultured in 35-mm Lux culture dishes (Miles Laboratories, Naperville, Ill) for seven days at 37° C and 5% CO_2 in air. Colonies with more than 20 cells were scored, and plating efficiency was described as PE_1. Four replicate plates were used to determine PE_1 for each assay.

Replating from methylcellulose Blast progenitors growing in methylcellulose were replated as described previously,[8] except for the substitution of HTB9-conditioned medium for PHA-LCM. Cell suspensions prepared from primary blast colonies in methylcellulose were washed twice in α-MEM and then replated at a concentration of 10^4 cells in .1 mL in Linbro microwells (Flow Laboratories, McLean, Va) of α-MEM with 20% FCS, 10% HTB9-conditioned medium, and .8% methylcellulose Colonies with more than 20 cells were scored after seven days' incubation, and their plating efficiency was designated as PE_2. Four replicate wells were used to determine PE_2. Secondary colonies have been shown to be similar to primaries in terms of growth requirements and cellular morphology by light and electron microscopy.[18]

Liquid suspension culture. Blast progenitors were cultured in liquid suspension as described previously,[6] modified by the substitution of HTB9-conditioned medium for PHA-LCM. T cell–depleted mononuclear cells from peripheral blood at a concentration of 10^6 mL were suspended in 3 mL of α-MEM supplemented with 20% FCS and 10% media conditioned by HTB9 cells The blasts were cultured in suspension in 35-mm Lux tissue culture dishes at 37° C in a humidified atmosphere of 5% CO_2 in air. Cultured cells were harvested and counted at day 7 Primary and secondary plating efficiencies (PE_1 and PE_2) were determined using the methylcellulose culture method described above.

Assessment of blast progenitor growth in suspension. The growth of clonogenic blasts in suspension was assessed by combining the methylcellulose assay with the suspension culture assay. After a period of time in suspension (usually seven days), the cells were harvested, washed, counted, and plated in methylcellulose to obtain the plating efficiency By multiplying the number of cells recovered from each dish by this plating efficiency, the number of clonogenic cells per dish was calculated. This value could be compared to the input of nucleated cells (see Figure 2, for example). For experiments where cells were replated serially, the dilution at each subculture could be used to calculate the cumulative growth of clonogenic blast cells with time (for an example, see Fig 8).

Sensitivity to Ara-C. Figure 1 illustrates the method used to measure the sensitivity of blast progenitors to Ara-C in suspension or in methylcellulose. Blast cells were placed in either culture condition

for seven days in the presence of increasing concentrations of Ara-C. At the end of the period, the suspension cultures were harvested, washed twice in a-MEM, and assayed for colony formation in methylcellulose in the absence of Ara-C. The recovery of clonogenic cells per dish was calculated as described above, and its decrease with increasing exposure to Ara-C in suspension was used to construct survival curves After seven days, the colonies in the methylcellulose cultures in the presence of drug were counted; the plating efficiency decreased as a function of drug dose, as described previously.[19,20] Thus two survival curves were obtained for the same cell population exposed to Ara-C for the same time period, but either in suspension or in methylcellulose

Sensitivity to Adriamycin. Similarly, the sensitivity of blast progenitors to Adriamycin was measured in suspension or methylcellulose cultures.[21] Two regimens were used In the first, the cells were exposed to varying concentrations of drug for ten minutes, washed, and cultured either in methylcellulose or in suspension. In the second, the cells were exposed continuously to the adriamycin during seven days' growth in methylcellulose or suspension cultures. In the latter instance, the cultures were washed before replating the cells in methylcellulose in the absence of Adriamycin

Cellular phenotypes Cellular phenotypes were determined by using several monoclonal antibodies. Among them, OKM-1,[22] 8OH.5,[23] and My-1[24] were used as reagents specific to granulopoietic cells. MO-2[25] was used as a reagent specific to monocytes.

Statistics. Group data were compared by Student's t test D_{10} values for Ara-C and Adriamycin were determined from the slope of negative exponential dose-response curves calculated by linear regression Dose-response curves were compared as described by Gaddum.[26] Data are presented as the mean ± SE. Jonckheere's test was done as described in Lehmann.[27]

RESULTS

Ara-C survival curves. Quantitative measurement of survival curves depends on the relationship between the number of cells added to cultures and the outcome of the procedure. Figure 2, representative of two experiments using samples containing sufficient blasts, shows this relationship to be linear for the number of blasts cells used to initiate suspension cultures and the recovery of clonogenic cells after seven days ($r = .971$, $P < .01$). Further, the presence of Ara-C in the cultures, while decreasing the yield of clonogenic blasts, did not alter the linearity of the relationship between blast input and clonogenic blast recovery ($P < .05$).

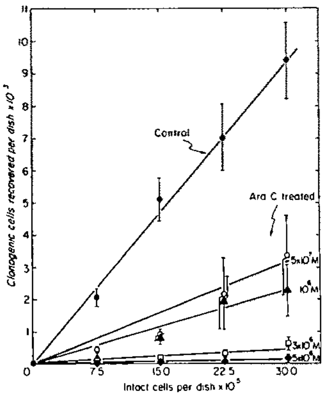

Fig 2. The relationship between the input intact cell numbers and the recovery of clonogenic cells after seven days of suspension culture in the absence of Ara-C (●) or presence of Ara-C at the doses of 5 × 10^{-7} (○), 1 × 10^{-6} (▲), 3 × 10^{-6} (□), and 5 × 10^{-6} mol/L (◆). Autologous irradiated cells were added to provide a fixed number of cells (3 × 10^{-5} per dish). The relationship is not significantly different from linear in the control and at all concentrations of Ara-C.

A typical Ara-C survival curve for blasts in suspension is shown in Fig 3. The simple negative exponential form of the curve is apparent. The survival curve obtained using the clonogenic assay, as described in Materials and Methods, is included in the figure. As reported previously,[19,20] such survival curves are also simple negative exponentials. Both results can therefore be described by a single parameter, the D_{10}. It is evident in Fig 3 that the D_{10} value was much greater for the clonogenic assay than for the suspension culture procedure.

The D_{10} values obtained for both methods are compared in

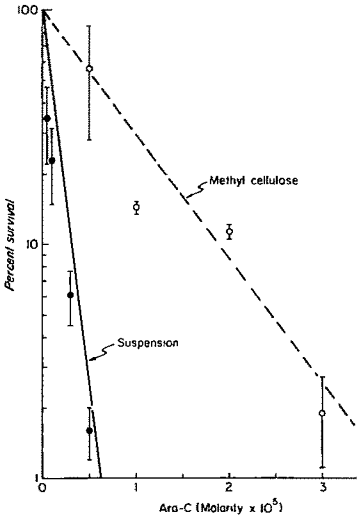

Fig 3. Ara-C survival curves for blasts in suspension (●) or methylcellulose (○) culture. Survival curves are simple negative exponentials. The curves may be described by the D_{10} value, the concentration of drug required to reduce survival to 10% of control.

Fig 4 No significant correlation was found between the two measurements ($r = .249$, $P > .25$) It is evident that the Ara-C survival curve measured in suspension was usually less than that obtained using the clonogenic assay. In one instance, patient 17, D_{10} in suspension was slightly greater than D_{10} in methylcellulose

Drug carry-over control. In the suspension culture methods, Ara-C is added to cultures at varying concentrations; after seven days, the cells are washed and replated in methylcellulose. It is possible, therefore, that Ara-C itself or an active metabolite might be carried from the suspension cultures into the methylcellulose assay plates. The action of such carried-over drug might explain the marked sensitivity observed with the suspension culture method.

Two experimental designs were used to test for this possibility. In the first, blast cells were exposed to Ara-C for seven days, recovered, washed, and irradiated to destroy their proliferative capacity. These were then added to varying numbers of intact cells, and the mixture was plated in methylcellulose. Colony formation as a function of the number of intact cells plated is shown in Fig 5A. It is evident that the plating efficiencies of clonogenic blasts in methylcellulose had not decreased when plated in the presence of cells that had been exposed to Ara-C under the conditions used to measure drug sensitivity in suspension.

In the second control design, irradiated cells obtained from cultures with or without Ara-C were added to varying numbers of intact cells, and the mixtures were cultured in suspension. Figure 5B shows the results obtained when the cells were tested for clonogenic blasts after seven days. The same linear relationship between input viable blasts and recovery of clonogenic blasts was maintained regardless of whether the irradiated supporting cells had been exposed to Ara-C or not.

These two experiments make carry-over of Ara-C an unlikely explanation for the differences in Ara-C survival curves seen when blasts were tested in suspension or in methylcellulose. In addition, the second design shows that exposure of blasts to Ara-C does not destroy their capacity to support the growth of small numbers of intact cells in suspension

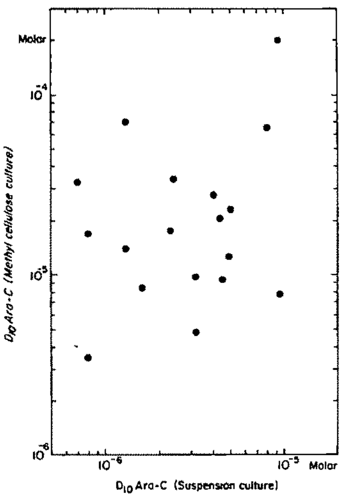

Fig 4. Relationship between D_{10} values in suspension and in methylcellulose cultures. There is no significant correlation ($P > .2$) r = 0.249.

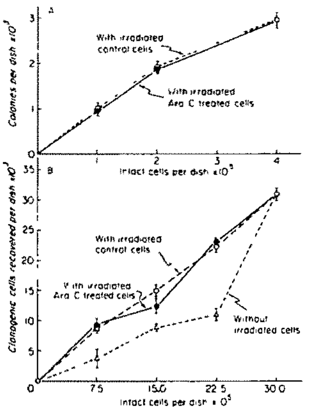

Fig 5. Drug carry-over experiments. Blast cells were exposed to Ara-C at the D_{10} dose for seven days in suspension culture. Then they were harvested, washed, and irradiated (20 Gy). They were added to intact blast cells in methylcellulose (A) or suspension culture (B) to provide a fixed cell number. As a control, blasts incubated in the absence of Ara-C were added. There was no significant difference between the effects of Ara-C-treated cells (●) and nontreated cells (○)

Adriamycin sensitivity. The comparison between Ara-C survival curves using two different methods is based on the assumption that both examine the same proliferative entity The requirement for a single growth unit in each is supported by the linear relationship between cells added to cultures and response shown for each method in Fig 2 and 5. Evidence has been presented that the two procedures display different properties of the same cell.[6] However, the possibility remains that a cell more primitive than the clonogenic blast detected in methylcellulose is growing in suspension and then undergoes a transition to a clonogenic blast when placed in methylcellulose. The existence of such a blast progenitor might explain the different Ara-C survival curves found in suspension and in methylcellulose. If this were the explanation, survival curves for a different drug might be expected to show the same phenomenon. Adriamycin is a candidate since marked patient-to-patient variation is found when Adriamycin survival curves are measured. Further, Adriamycin differs from Ara-C in its effects on the composition of colonies surviving drug exposure. Colonies in Ara-C-treated plates often contain fewer new clonogenic cells than controls;[9] in contrast, the PE_2 values for colonies developing after Adriamycin treatment are similar to control values. These data have been interpreted as indicating that cell-cycle processes required for self-renewal might be more sensitive to Ara-C than those that serve cell division generally.[13]

Blast progenitor survival curves for Adriamycin are shown in Fig 6 In the experiment, either cell suspensions were exposed briefly to drug, or Adriamycin was included in the culture medium.[21] It is apparent that much greater sensitivities were found with the latter procedure However, regardless of the length of exposure of cells to Adriamycin, very

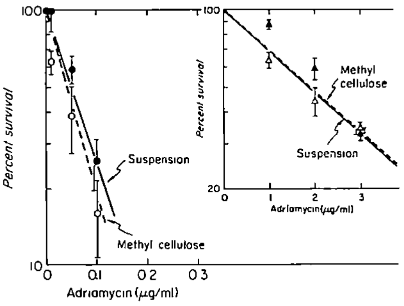

Fig 6. Adriamycin dose survival curves. Adriamycin was added to suspension culture and methylcellulose culture. Survival curves are simple negative exponentials. The insert shows the effect of brief exposure (ten minutes) to Adriamycin. Survival curves in suspension and in methylcellulose were indistinguishable.

similar D_{10} values were obtained both with the methylcellulose procedure and after growth in suspension. This finding supports the view that the growth unit is the same or very similar in both the suspension and methylcellulose assays and strengthens the basis for comparing survival curves obtained by the two methods.

Association with outcome. In our previous studies, D_{10} Ara-C measured in methylcellulose was not an attribute contributing to variation in outcome.[10] This conclusion was based on clinical data from patients treated with multidrug regimens and using the assay for colony formation in methylcellulose. Although sensitivity data are available for only 15 patients treated with high-dose Ara-C at the time of first diagnosis, we undertook to compare the association of successful remission induction with D_{10} values measured either in suspension or in methylcellulose (Fig 7). When we followed our usual practice (see Materials and Methods) by including in the analysis all patients who received at least one dose of drug and by considering partial remissions as responses, a significant association ($P < .01$) (see Materials and Methods) was found for D_{10} values in suspension but not in the 14 samples assayed in methylcellulose ($P > .2$). Additional analyses were done after removal from the data set of patients who died within the first 48 hours of treatment. In the first of these analyses partial remissions were not included; significant association was maintained between low D_{10} values in suspension culture and successful remission induction ($P < .05$) but not for the methylcellulose assay ($P > .2$). Only if the two patients with partial remission were considered as failures did the association of D_{10} value in suspension with remission induction lose significance. It seems inappropriate to add the partially responding patients to the failure group, since, following treatment with Ara-C, blasts were reduced in these patients and normal hematopoiesis improved It may be more useful to group the patients is three sets: remission, partial remission, and failure (excluding early deaths) Then the D_{10} values for each set can be compared using Jonckheere's test,[27] which is the appropriate statistic to determine if sets are ordered in ascending values of D_{10} (that is, D_{10} CR < D_{10} PR < D_{10} failure). This analysis showed that such ranking is significant for these data ($P < .05$). This finding is consistent with the hypothesis that increasing D_{10} values in suspension are associated with decreasing probability of responding to treatment. Jonckheere's test did not give significant P values when applied to the D_{10} values measured in methylcellulose.

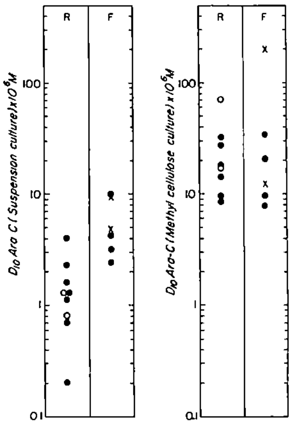

Fig 7. Comparison of patients who responded (R; completely, ●; partially, O) or failed (F) treatment with high-dose Ara-C administered at diagnosis. Early deaths are shown as X. The D_{10} values are shown on the horizontal axis. The two columns at the left contain the results obtained using the suspension culture method. The columns at the right contain the values obtained using the methylcellulose assay. See the text for a description of the analysis.

We considered other factors that have been found to be associated with outcome. In Table 2, age, number of blasts per milliliter in the peripheral blood, platelet count, and plating efficiencies in methylcellulose (PE_1 and PE_2) are compared with D_{10} Ara-C in suspension; the results of testing these attributes for an association with successful remission induction are included in the table. As in previous studies,[8,10] a significant association was found between PE_2 and response; PE_2 was also correlated with D_{10} Ara-C in suspension. None of the other characteristics of patients or of their disease were associated with outcome of treatment or with D_{10} Ara-C in suspension. These patients were all treated with large doses of Ara-C (see Materials and Methods); not surprisingly, blasts were cleared from the peripheral blood in all patients who received a full initial course of treatment, including those who failed to respond (Table 3). It may be, therefore, that the association between low D_{10} Ara-C values, measured in suspension, and successful remission induction is based on some drug action in addition to general cytotoxicity.

Repeated exposures to Ara-C. A major advantage of the suspension culture is that some blast populations may be

*Blasts were predominant in a cellular bone marrow 4 weeks after treatment, but no further assessment was conducted before death

maintained in the culture for periods of weeks. This permits the examination of the effects of repeated exposures to chemotherapeutic agents, a setting that mimics the clinical use of drugs. Figure 8 displays the results of an experiment in which blast cells were exposed to Ara-C repeatedly over a period of 238 days. Two doses were used, 10^{-7} and 10^{-6} mol/L; the Ara-C was added at the time of subculture, and the cells were not washed until the next scheduled change of medium, 1 week later. Thus the drug exposure schedules were the same as those used to measure Ara-C survival curves

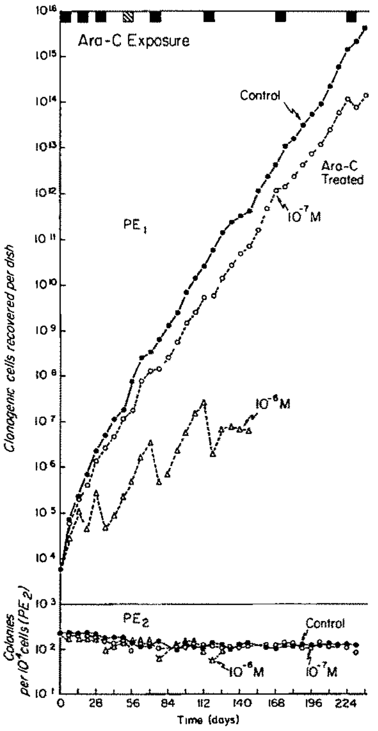

Fig 8. Repeated exposure of blasts from patient 18 during prolonged culture in suspension. The cells were grown for seven days, counted, washed, diluted to a concentration of 10^6/mL, and recultured. The curves in the top panel of the figure were constructed by accumulating the growth at each subculture. Control cultures are shown as ●——●. Cells were exposed to Ara-C at the times shown at the top of the figure. Those exposed to 10^{-7} mol/L (O——O) Ara-C were treated at each time indicated. Those exposed to 10^{-6} mol/L (Δ——Δ) did not receive drug at the time indicated by ▨ since recovery was not then sufficient. The PE_2 values for the three groups are shown in the bottom panel, using the same symbols as in the top panel.

It is evident that the control cultures grew exponentially, with a doubling time of between three and four days At the lower drug dose, growth was inhibited immediately following exposure but resumed after the next subculture. In the cultures that received Ara-C at the 10^{-6} mol/L dose, a fall in clonogenic cells was seen after each exposure, followed by a resumption of growth after the cells were washed and resuspended.

We looked for changes in blast cell properties following repeated drug exposure. At the high dose, the degree of fall in clonogenic blasts was similar following each exposure, indicating that sensitivity to Ara-C had not changed. Sufficient cells were available from the control cultures and those exposed to 10^{-7} mol/L Ara-C to permit the construction of detailed survival curves. After 96 days in culture, the D_{10} values were 2.4×10^{-6} and 3.4×10^{-6} mol/L for the control and drug-exposed cultures, respectively. These values are not significantly different ($P > .05$). At day 189, the blast progenitors remained Ara-C-sensitive, with a D_{10} for the 10^7 mol/L Ara-C-treated cultures of 1.5×10^{-6} mol/L. The morphology of the cells remained unchanged throughout; in excess of 70% were typical blast cells; the remainder showed some granulation and occasional segmented forms were seen. The predominant immunologically defined markers on the blasts were those associated with granulopoietic cells and macrophages (OKM-1, 8OH.5, My-1, and MO-2); their frequencies did not change during long-term culture, nor were there differences in morphology or marker-defined phenotype between control and Ara-C-treated blast populations.

After 10 weeks in culture, the growth requirements were retested; the need for HTB9-conditioned medium and a cell density of 10^6 cells/mL had not changed. We conclude that in this experiment, repeated exposures to Ara-C did not lead to drug resistance or other phenotypic changes in the blast population.

DISCUSSION

We have shown that the dose-response curve for the effect of Ara-C on AML blasts is dependent on the method used to measure it. Blasts exposed to drug in suspension culture were usually more sensitive than when Ara-C was present during colony formation in methylcellulose. This difference may relfect the mechanism's underlying growth in suspension on the one hand and colony formation on the other. For the former, data are available consistent with the view that growth of clonogenic blasts in suspension reflects their self-renewal rather than recruitment from another population.[6] In contrast, the scarcity of new clonogenic cells in blast colonies has been interpreted to mean that terminal divisions predominate during colony formation.

The finding of uniform sensitivity to Adriamycin in suspension and methylcellulose makes it unlikely that methylcellulose protects cells against drugs by acting as a barrier. Rather, the different effects of culture conditions on the dose-response curves for Ara-C and Adriamycin may reflect their actions on cells; Adriamycin may reduce cell proliferation generally, while Ara-C may have additional toxicity for genetic mechanisms required during self-renewal. From this view point, Adriamycin dose-response curves might be expected to be similar in any assay that depended on cell proliferation, while Ara-C might appear more toxic in an assay that reflects self-renewal.

This hypothesis may be considered in light of the associations of blast properties with remission induction. Low values of PE_2 have been correlated repeatedly with successful remission induction.[8,9,16] Although the small number of patients available for analysis limits the power of the statistical tests, an association is emerging between low Ara-C D_{10} values in suspension and success of treatment with Ara-C. In contrast, for the same series of patients, analyzed by the same statistical methods, no association with response was found when drug sensitivity was measured using colony formation in methylcellulose as an assay. It seems unlikely that drug cytotoxicity in itself would explain an association between response and sensitivity in suspension but not in methylcellulose. The doses of Ara-C adminstered to the patients were high enough to ensure that blasts were cleared from the peripheral blood even in those failing treatment, making it improbable that insufficient cell kill explained failure to achieve remission in the four failing patients who received adequate courses of Ara-C. Rather, sensitivity in suspension may improve response not only through general cytotoxicity but also by interacting with some other component of blast cell function. It is attractive to suggest that this function might be self-renewal. Then the associations with successful treatment of both low PE_2 and sensitivity to Ara-C in suspension might have a similar basis. A large prospective study is needed to evaluate the contributions of PE_2 and Ara-C sensitivity in suspension, using multivariate methods.

We have demonstrated the feasibility of exposing blast cells to chemotherapy repeatedly. The data of Fig 8 support a simple cytotoxic model of chemotherapy. At low doses, the doubling time of the blasts was prolonged; at a high dose, reduction of clonogenic blasts was seen after each exposure, followed by regrowth and eventually cessation of proliferation. For this dose, the extent of the reduction was similar after each exposure, indicating that Ara-C sensitivity had not changed. At the lower dose, sufficient cells were available to construct survival curves. The D_{10} values were not significantly different ($P > .05$). Thus we did not obtain evidence of the emergence of drug-resistant cells. The morphology and immunologically defined phenotypes of the blast population remained similar in the treated and control groups. No evidence of increased differentiation was seen It is noted, however, that this experiment, though requiring a massive effort over 238 days, is but a single example. It needs to be repeated with other blast populations and using other schedules. Our results show only that cells in culture can be used to model the repeated drug exposures used in treatment.

Finally, a major conclusion from these data has certain consequences for the assessment of chemotherapy using cell culture methods. It is evident that the dose-response curve for any agent may be dependent on the method used to determine it, even when techniques are compared that reflect drug effects on cell proliferation. It follows that the use of such dose-response curves, whether for predicting outcome of treatment or selecting drugs, will be most effective if the mechanisms underlying the assay procedures are understood.

Bone Marrow Transplantation in Patients Aged 45 Years and Older

By Hans-G. Klingemann, Rainer Storb, Alexander Fefer, H. Joachim Deeg, Frederick R. Appelbaum, C. Dean Buckner, Martin A. Cheever, Philip D. Greenberg, Patricia S. Stewart, Keith M. Sullivan, Robert P. Witherspoon, and E. Donnall Thomas

Increasing age has been reported to be a poor prognostic factor for survival after bone marrow transplantation. We evaluated causes of death and frequency and type of complications after marrow grafting in 24 syngeneic and 39 allogeneic recipients who were 45 to 68 years old at the time of transplant. Most patients were in an advanced stage of hematologic malignancy. Among patients given syngeneic transplants, actuarial disease-free survival at 7 years is 20%. The major causes of death were relapse of leukemia and idiopathic interstitial pneumonia. Among allogeneic recipients, 9 (23%) are currently alive, and actuarial disease-free survival at 7 years is 11%. Cytomegalovirus pneumonia and septicemia were the most frequent causes of death. Patients over 50 years of age had the poorest survival rate (1/13), but many of these were transplanted in an advanced stage of their disease. However, among 12 patients transplanted while in remission or at an early stage of their disease, 5 are surviving 65 to 1,160 days after transplantation, with an actuarial survival rate of 22% at 3 years. This is in contrast to those who received their transplant in relapse: 2 out of 20 patients (10%) became long-term survivors, with a probability of survival of 15% at 3 years.

The actuarial incidence of grade II through IV acute graft-*v*-host disease (GVHD) was 30% for allogeneic recipients 45 to 50 years of age. This was not significantly different from the incidence in younger patients. In patients 51 to 62 years of age, the actuarial incidence of acute GVHD was 79%; however, this group included three partially HLA-mismatched transplants. Ten of 15 patients surviving at least 3 months developed chronic GVHD.

These results suggest that marrow transplantation is feasible and should be considered in patients over 45 years, especially if recipients are in good clinical condition and are at an early stage of their disease, such as the chronic phase of chronic myelogenous leukemia and preleukemia. For patients more than 50 years of age, allogeneic marrow grafting cannot presently be considered first-line therapy.

HIGH-DOSE CHEMORADIOTHERAPY followed by marrow transplantation is an effective therapeutic approach for patients with aplastic anemia and hematologic malignancies. About 75% of patients with aplastic anemia and 50% with acute (AML) or chronic myeloid leukemia (CML) can apparently be cured if marrow grafting is performed early in the course of the disease.[1–7] Many centers, however, will not accept patients over 40 or 45 years of age for this form of therapy because increasing age has been reported to be associated with an increased incidence of morbidity and mortality after marrow transplantation.[8–11]

The purpose of the present retrospective analysis was to determine the spectrum and frequency of transplant-related complications and the survival rate and causes of death in patients 45 years and older who received an allogeneic or syngeneic marrow graft in Seattle after 1977. Studies with intensive conventional chemotherapy in acute myeloid leukemia have shown that patients over 60 years of age are able to tolerate intensive chemotherapy.[12–14] The data from our study indicate that older patients can benefit from bone marrow transplantation as well, especially for CML in the chronic phase and preleukemia. However, in patients more than 50 years of age, the incidence of transplantation-related complications such as interstitial pneumonia and acute graft-*v*-host disease (GVHD) increases significantly.

MATERIALS AND METHODS

Between January 1, 1978, and December 1, 1984, 56 patients who were 45 to 68 years of age underwent marrow transplantation for hematologic malignancy, 4 for aplastic anemia, and 3 for preleukemia Patient characteristics are summarized in Table 1. Twenty-four patients received marrow from a monozygotic (syngeneic) twin donor, and 39 received allogeneic marrow from an HLA-identical (n = 34) or HLA-partially incompatible sibling or other relative (n = 4). One patient (unique patient number [UPN] 2588) was transplanted from an unrelated, HLA-phenotypically identical and mixed lymphocyte culture (MLC)-nonreactive donor. Patients who received an allogeneic marrow graft were arbitrarily subdivided into two groups according to age (group 1, 45 to 50 years; group 2, 51 to 62 years of age). In addition, we analyzed the actuarial disease-free survival of 153 patients aged 30 to 44 as well as 138 patients aged 20 to 29 who received an allogeneic transplant from an HLA-matched sibling during the same period of time. To allow for a comparison with patients over 45 years of age, we divided these patients into those considered a "good risk" (AML in first remission, CML in chronic phase, preleukemia) and those considered at "high risk" (AML in relapse or second or subsequent remission, CML in accelerated phase or blast crisis) at the time of marrow grafting. Details of the transplantation procedure have been described elsewhere.[15] Patients with aplastic anemia were conditioned for grafting with cyclophosphamide (Cy), 50 mg/kg/d on each of four successive days. Patients with a hematologic malignancy were conditioned with a combination of Cy 60 mg/kg on each of two successive days followed by total body irradiation (TBI) delivered from dual ^{60}Co sources at an exposure rate of 5 to 8 cGy/min Allogeneic recipients received either methotrexate (MTX) or cyclosporine (CSP) for GVHD prophylaxis [16–18] Eight patients were given marrow that had been treated in vitro with monoclonal antibodies and complement.[19]

*Mean (range)

Acute and chronic GVHD were graded and treated as described.[20-23] The diagnosis of veno-occlusive disease (VOD) of the liver was made according to previously established criteria.[24] Diagnosis of interstitial pneumonia versus pneumonia due to bacterial or fungal infection was generally made by open-lung biopsy or at autopsy. Methods of assessment of engraftment have been described previously.[20] Marrow transplantation protocols and consent forms for these studies were approved by the Institutional Review Boards of the Fred Hutchinson Cancer Research Center or the University of Washington School of Medicine Data were evaluated as of February 1, 1985

RESULTS

Syngeneic transplants. Sixteen of 24 recipients of syngeneic grafts have died; the remaining 8 (33%) are surviving 476 to 2,412 days after grafting (Table 2) Actuarial disease-free survival was 20% at 7 years (Fig 1). Of the 8 survivors, 5 are well (Karnofsky score 100%) and 3 have suffered a ralapse of leukemia. Deaths were mainly due to relapse (6 patients) and idiopathic interstitial pneumonia (3 patients). Only one syngeneic recipient developed VOD of the liver, even though all but one (UPN 967) received at least 10 Gy TBI in combination with high-dose chemotherapy.

Allogeneic transplants. Actuarial survival of all 39 patients was 11% at 7 years (Fig 1).

In group 1 (45 to 50 years old), 8 of 26 patients (31%) are surviving, 1 in leukemic relapse, 4 with chronic GVHD, and 3 without complications (Karnofsky score 90% to 100%). Six patients (23%) died of cytomegalovirus (CMV) pneumonia, 7 (27%) from bacterial or fungal septicemia (Fig 2), and 9 from miscellaneous causes (Table 3). Five patients developed clinical evidence of VOD of the liver, but this was lethal in none. In group 2 (51 to 62 years old), 12 of 13 patients have died and 1 is alive 95 days after transplantation. Causes of death are listed in Table 4. Three patients had a leukemic relapse. Eight patients (62%) developed interstitial pneumonia (IP), due to CMV in 3 patients and of undefined etiology in 5 patients (Fig 2) All but one died. VOD of the liver was present in 3 patients but lethal in none. Of 9 patients with leukemia in this group, 7 were transplanted while in relapse or accelerated phase of the disease. With regard to other transplant-related problems, there was no difference between patients in groups 1 and 2.

Five of 12 "good risk" patients (41.5%) in groups 1 and 2 (AML in first remission, CML in chronic phase, preleukemia) are alive; 4 are well, 1 is alive but relapsed (UPN 2527), and 2 have chronic GVHD. Actuarial disease-free survival of these patients was 22% at 3 years (Fig 3). However, of 20 "high risk" patients transplanted (2 patients with aplastic anemia and 5 patients given HLA-incompatible transplants were excluded), only 2 (10%) became long-term survivors, with an actuarial disease-free survival at 3 years of 15%. Among 8 patients transplanted for AML in first remission, only 1 is alive and well, 1 is alive after relapse, and 6 have

died of various causes. However, of 5 patients transplanted in chronic phase of CML, 3 are alive and well.

For the purpose of comparison, 153 patients aged 30 to 44 years and 138 patients aged 20 to 29 years were evaluated for survival. Figure 4 represents the Kaplan-Meier plots of disease-free survival for both "good risk" and "high risk" patients. At 3 years there were no differences among the "high risk" patients of all age groups. However, the younger patients (20 to 29 years) with a favorable diagnosis at transplant ("good risk") had a better survival rate than recipients older than 30 years: 48% for patients aged 20 to 29 years, 29% for patients aged 30 to 44 years, and 22% for those over 44 years. Overall long-term survival of patients aged 20 to 29 years and 30 to 44 years did not differ. Furthermore, survival curves of "high risk" patients of different age groups did not show any significant survival advantage for a particular age group after 3 years.

In terms of cardiac complications, two recipients developed atrial fibrillation, which was successfully treated. One patient (UPN 1090) presumably died from a cardiac arrhythmia. One patient (UPN 1821) suffered from cardiomegaly and pericardial effusion during conditioning therapy, but this problem resolved subsequently.

Regarding the actuarial incidence of acute GVHD, only patients surviving beyond day 21 after marrow grafting were evaluated. Recipients who died earlier were censored on the Kaplan-Meier plot. The actuarial probability of acute GVHD of grades II through IV was 30% in group 1 and 79% in group 2. This difference was statistically significant ($P < .05$, Fisher's exact test). Furthermore, the onset of acute GVHD was earlier in group 2 than in group 1 ($P < .05$,

DISCUSSION

Marrow transplantation offers the chance for long-term survival and possibly cure for patients with a hematologic malignancy or aplastic anemia. However, applicability may be limited by several factors including patient age. Numerous studies have shown an increase of transplantation-related complications in older patients,[8–11] and most centers will not accept patients over 40 or 45 years of age for transplantation. It is not clear, however, whether it is judicious to exclude all patients from marrow grafting because of an arbitrarily chosen age limit.

In the present retrospective review, we analyzed our results with syngeneic and allogeneic bone marrow transplantation in 63 consecutive patients 45 to 68 years of age. Some encouraging results and several problems were noted. The frequency of pulmonary complications presumably related to chemoradiotherapy was high in allogeneic recipients of more than 50 years of age. Eight of 13 recipients (62%) developed pulmonary complications, and 7 died of respiratory failure. The incidence of interstitial pneumonia in patients between 45 and 50 years of age (23%) was not different from the incidence in younger age groups.[25,26] One could speculate that the lungs of older patients are increasingly susceptible to respiratory complications caused by aggressive conditioning regimens. However, nearly all patients over 50 years of age were transplanted in an advanced stage of leukemia and had received multiple cycles of pretransplant chemotherapy, circumstances under which interstitial pneumonia appears to be more common regardless of age.[11,26] It is also of note that of 8 patients transplanted in first remission of AML, only 1 is alive and well, in contrast to 3 of 5 recipients grafted for CML in chronic phase. This might point once more to the negative impact of previous chemotherapy, particularly in elderly patients, since patients with CML in chronic phase usually receive less intensive treatment prior to marrow grafting.

The observation that "high risk" patients over 44 years of age had a survival rate comparable to that of recipients 30 to 44 years of age may be important when counseling older patients. A comparison between "good risk" patients beyond 3 years after grafting is not possible, since the longest survivor over 44 years of age is only 3 years after transplantation. At 3 years, however, actuarial disease-free survival is not statistically different. These data suggest that a negative effect of age on prognosis after marrow transplantation becomes prominent already around age 30. Thus survival of patients transplanted when 45 years of age or older, although inferior to that in patients less than 30 years of age, may not

¶Donor differed from recipient for two HLA antigens

**Transplanted from an HLA-phenotypically unrelated donor.

differ significantly from that in patients of the intermediate age group (30 to 44 years old).

Another concern in older patients was the development of hepatic VOD, since a previous study had shown that the risk of VOD increased with patient age.[24] In the present population of older patients, however, the incidence of VOD was not increased in comparison to younger patients, and, in fact, only 1 of 24 recipients of a syngeneic transplant developed VOD. Since VOD is not thought to be mediated by an immunologic process, this low incidence is surprising. However, the small numbers of patients do not allow for a more detailed statistical analysis.

The frequency of infectious complications early after transplantation was high. One possible explanation for this finding might be a reduced thymus function. Thymus involution begins at about 20 years of age, and circulating levels of thymic hormones are decreased;[27] this could result in a defective maturation of lymphoid cells derived from the transplanted marrow.

The actuarial incidence of acute GVHD for patients 45 to

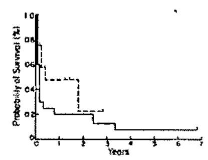

Fig 3 Kaplan-Meier product-limit estimates of disease-free survival in 12 patients aged 45 years and older who received an HLA-identical allogeneic transplant for AML in first remission, CML in chronic phase, or preleukemia ("good risk"; dashed line) compared to those patients (n – 20) who were at "high risk" at transplant (acute leukemia in relapse or second or later remission, CML in accelerated phase or blast crisis; solid line). Tick marks indicate surviving patients.

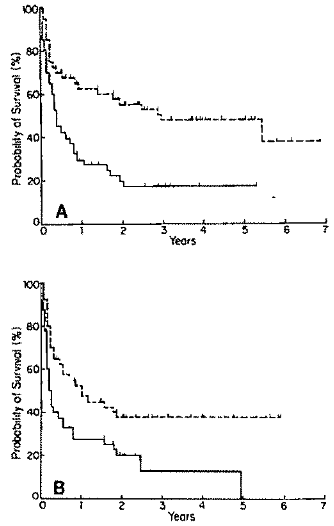

Fig 4. Kaplan-Meier product-limit estimates of disease-free survival in patients between ages 20 and 29 (A) and ages 30 and 44, (B), categorized by recipient risk at transplant ("good risk," dashed line; "high risk," solid line; see Fig 3) between January 1, 1978, and December 1, 1984.

50 years of age was similar to that observed in recent studies in younger patients[5,16,18,22] In patients over 50 years of age, however, the incidence of acute GVHD was high (79.5% grades II through IV). Because of the small number of patients and the fact that three had received partially matched transplants, these data should be interpreted cautiously. Somewhat surprisingly, chronic GVHD was neither more frequent nor more severe than in younger patients.[22]

Although this retrospective analysis deals with a heterogenous patient population (including T cell–depleted marrow transplantation and HLA–partially matched grafts), some preliminary conclusions can be drawn from these data. Marrow transplantation can be carried out successfully in patients aged 45 and over, albeit with a higher morbidity, especially with regard to interstitial pneumonia, acute GVHD, and various infectious complications. As in other age groups, recipients of syngeneic transplants did somewhat better than recipients of allogeneic transplants, but relapse of leukemia was still a significant problem.

Problems were apparent particularly in patients over 50 years of age, possibly because of a bias toward poorer-risk patients in this group. Therefore, patients with leukemia who are over 45 years of age and have an identical-twin donor are definitely candidates for marrow transplantation. With an allogeneic donor, selected patients may be considered for marrow grafting: Patients with CML in chronic phase seem to benefit from allogenic marrow grafting, as do patients with preleukemia. However, patients with acute leukemia at the present time should be considered for transplantation only at first relapse rather than in first remission.

The number of patients with aplastic anemia was too small to draw any final conclusions. Since immunosuppressive therapy has been reported to have a 40% to 60% response rate,[28,29] it might be reasonable to try this treatment first before proceeding to allogeneic marrow grafting.

Short-Term Culture of Acute Myeloid Leukemia Blasts: Analysis of Acquired Susceptibility to Activated Natural Killer Cells

By Philippe Moingeon, Arnaud Ythier, Alexandre Nowill, Laurence Delmon, Chantal Bayle, José-Luis Pico, Claude Bohuon, and Thierry Hercend

Following a cryopreservation step, short-term cultures of circulating leukemic blasts from a patient with acute myeloid leukemia (AML) were performed. Because cultured tumor cells became susceptible to natural killer (NK) activity, in vitro alteration of the blasts was studied. Immediately after thawing, cell suspensions consisted of a relatively homogeneous population of undifferentiated blasts. In culture, tritiated thymidine uptake by the leukemic cells was low during the first 24 hours and then increased (×20) to a peak on day 7. The cell concentration started to increase on day 4. On day 8, <10% of the cultured cells still appeared as undifferentiated blasts, whereas up to 60% were granular and 30% to 40% had a monocytoid morphology. Prior to being cultured, the blasts were resistant to resting and IL2-activated natural killing. When the kinetics of in vitro acquired susceptibility were studied, it was found that maximum cytotoxicity against these leukemic cells was reached within 24 hours. Thus, the blasts had become NK-sensitive prior to increase in DNA synthesis, proliferation, and differentiation based on morphological and cytochemical criteria. In contrast, there was a positive correlation between acquired susceptibility and surface expression of an activation antigen, termed TNKtar. To dissect further the mechanisms of acquired susceptibility, a series of six NK clones representing four distinct phenotypes of NK active lymphocytes were tested against the leukemic cells. Immediately after thawing, blasts were essentially resistant to all clones, whereas they were strongly killed by 5 of 6 clones when cultured for 24 hours. Cold target inhibition assays indicated that resistance of fresh blasts was likely to be due to a binding defect. These results suggested that tumor cells became susceptible because they surface-expressed NK target structure(s) in the early phase of an activation process leading to their proliferation and/or differentiation. This hypothesis was substantiated for one clone, termed JT9, because the anti-TNKtar antibody blocked cytotoxicity of JT9 cells against the cultured blasts.

© *1986 by Grune & Stratton, Inc.*

USING long-term cultured hematopoietic cell lines such as K562, a series of studies have been performed to correlate stages of target cell differentiation and susceptibility to natural killer (NK) activity.[1–3] Various agents, including sodium butyrate and phorbol esters, were used to obtain further differentiated and well-characterized phenotypes of K562 cells, which were then tested as target cells for human peripheral blood NK active lymphocytes. When cytotoxicity against either untreated or differentiated K562 cells was compared, it was found that the latter were less sensitive. Because for example, certain highly differentiated tumors (ie, myelomas) are quite susceptible to natural killing, it has been pointed out that results obtained with K562 cells should not be interpreted in a simplistic fashion.[1] However, these experiments demonstrated that cellular events leading to varying differentiation stages of a particular cell type are important in determining susceptibility to NK cells. Moreover, they pointed out that in vitro experimental systems in which cell alteration is carefully monitored may be of great interest in dissecting the mechanisms by which NK active lymphocytes can recognize and kill tumor cells.

We analyzed a situation in which undifferentiated fresh leukemic blasts resistant to NK cells became susceptible following a short-term culture. A series of biological parameters was investigated for an eight-day period. A large fraction of cultured leukemic blasts underwent an activation process leading to proliferation and/or differentiation. However, NK susceptibility was acquired very early (within 24 hours of culture), prior to both increased DNA synthesis and detectable morphological changes. Experiments performed with well-characterized NK clones strongly suggested that early expression of unique surface antigens, in the context of tumor cell activation, represented a necessary signal for target recognition and subsequent lysis.

MATERIAL AND METHODS

Case report A 19-year-old woman was admitted to the Hematology Unit of Institut Gustave-Roussy for acute myeloblastic leukemia, type M1, according to French-American-British (FAB) classification. The initial WBC count was 104,000/μL Between April and November 1984, the patient received two successive courses of daunorubicin, vincristine, and Ara-C, two courses of Ara-C plus *m*-AMSA, two courses of etoposide, *m*-AMSA, and melphalan and, finally, one cycle of therapy combining aclacynomycine and 6-thioguanine Because complete remission was not achieved, we decided to administer symptomatic treatment.

In vitro culture of leukemic cells Prior to therapy, 2×10^9 leukemic cells were obtained following Ficoll-Hypaque density gradient centrifugation. These cells were immediately cryopreserved (50 vials containing 40×10^6 cells) in the presence of a final concentration of 10% dimethyl sulfoxide (DMSO). Cells were thawed in RPMI containing 2.5% human AB serum and then seeded at 3×10^5 cells per milliliter in culture medium containing 15% human AB serum, 1% penicillin-streptomycin; 1% sodium pyruvate, and 2% L-glutamine In this article, cells studied immediately after thawing are termed "fresh" or "day 0" blasts. For morphological and cytochemical studies, cytocentrifuge smears were stained with

May-Grunwald-Giemsa, Sudan black B, and α naphtyl-butyrate esterase.

Thymidine incorporation and cell cycle analysis. For thymidine incorporation assays, cells were seeded at 50,000 cells per well in round-bottomed microtiter plates Experiments were done in culture medium. Cultures were pulsed as described in the Results section with 0 2 μCI of tritiated thymidine and, subsequently harvested on a MASH II apparatus Tritiated thymidine incorporation was measured using a liquid scintillation counter For cell cycle analysis 1 × 10^6 day 0, day 1, and day 2 leukemia cells, and 1 × 10^6 peripheral blood mononuclear cells (PBMCs) from a normal donor were treated in parallel They were fixed with 1% formaldehyde in phosphate-buffered saline (PBS). Ethidium bromide (Calbiochem, San Diego, Calif) was added, to a concentration of 80 μg/mL. After ten minutes of equilibration at room temperature, cells were analyzed on a Becton Dickinson FACS IV. Intensity of fluorescence was determined by analyzing 10,000 cells per sample.

Immunofluorescence assays and cytofluorometric analysis. Phenotypic analysis was performed by indirect immunofluorescence with fluorescein-conjugated goat anti-mouse immunoglobulin (Coulter Immunology, Hialeah, Fla), as previously described.[4] Samples were analyzed either on an Epics V flow cytometer (Coulter Electronics) or a FACS 440 (Becton Dickinson). Each sample contained 10,000 cells. Histograms display the number of cells (ordinate) *v* the intensity of fluorescence (abscissa). The negative control used to determine background fluorescence was an ascites containing an antibody previously shown not to react with the tested cells (ie, anti-B1 for NK clones)

Cytotoxicity assays. Cytotoxicity assays were performed in four hours against chromium-labeled target cells. All experiments were done in culture medium using V-bottomed microtiter plates according to a standard method Percentage of specific cytotoxicity was calculated as previously described.[4] Purified recombinant IL-2 (Biogen) used to activate resting NK cells from normal donors was used at a final concentration of 70 ng/mL.

Uncloned effector cells. PBMCs from healthy donors were separated by Ficoll-Hypaque density-gradient centrifugation Cell suspensions enriched in NK activity were obtained from PBMCs by centrifugation on discontinuous density gradients of Percoll after a step of adherence on nylon wool columns.[5] Gradients consisted of six layers ranging from 47% to 31% Percoll. Under our experimental conditions, fraction 3 consistently contained >65% large granular lymphocytes and was used for the cytotoxicity assays shown in Table 1. Fraction 5 consistently contained >90% small lymphocytes and was used as a negative control.

Human NK clones Methods for generation of human NK cloned cell lines have been described in detail.[4,6,7] In brief, for initial cloning cells are usually seeded at 1 or 0.5 cells per well on a feeder layer of autologous or allogeneic irradiated (5,000 rad) PBMCs plus PHA (2 μg/mL) and/or allogeneic irradiated (5,000 rad) Epstein-Barr virus (EBV)-transformed B cells Colonies are expanded by addition of culture medium containing leukocyte-conditioned medium (LCM) (10%–15% final dilution) every three days LCM is produced following stimulation of whole PBMCs at a concentration of 2.5 × 10^6 cells per milliliter by a combination of phytohemagglutinin (PHA), phorbol myristate acetate (PMA), and irradiated EBV-transformed B cells as previously described.[4] Cells are washed four times after three hours to remove the mitogens, and supernatants are harvested after 40 hours of incubation at 37 °C.

All clones described in these studies have been subcloned at least three times at 100 cells per well. They all have homogeneous phenotypes when tested with a series of monoclonal antibodies. Phenotypes are stable and have been controlled after each subcloning procedure. Of the clones used in these studies, JT3 and JT9 have been previously described in detail.[6,7] TC12, TC48, 50, and 59 have been derived from peripheral blood lymphocytes of a leukemic patient during early reconstitution following allogeneic bone marrow transplantation Cell surface phenotypes have been determined using indirect immunofluorescent assays and subsequent cytofluorometric analysis. Anti-T3 defines all mature T lymphocytes in human peripheral blood [8] T4 and T8 antigens are expressed on reciprocal subpopulations of circulating T lymphocytes.[9,10] Anti-T11 defines an antigen associated with the sheep erythrocyte receptor.[11] NKH1A is a pan NK-associated marker, whereas NKH2 is expressed on a subpopulation of circulating LGL and a fraction of human NK clones [12] The reactivity of the clones with these six monoclonal antibodies (Mabs) is shown in Table 1A. All Mabs reacted with either <5% or >90% of cloned cells in each case As shown in Table 1, TC48 represents an uncommon lymphocyte reacting only with anti-NKH1A. JT9 cells[7] have a mature T cell phenotype coexpressing T3, T8, and T11. However, as opposed to conventional T lymphocytes, JT9 cells are NKH1A+. JT3 and TC59 have usual NK phenotypes, both being T3−, T11+, NKH1A+, NKH2+. TC12 and T50 are also T3−, T11+, and NKH1A+ but, as opposed to JT3 or TC59, these clones do not express NKH2. Functionally, these six clones are strongly cytotoxic against K562 and JM (Table 1B), used here as conventional, highly susceptible NK target cell lines For optimal standardization, experiments were repeatedly performed with identical aliquots of thawed cloned effector cells.

RESULTS

Morphological and cytochemical analysis of fresh and in vitro cultured leukemia cells. Fresh peripheral blood leukemic blasts were cultured after a cryopreservation step and subsequent thawing First, it was macroscopically evident that at least a fraction of the cells started to divide within a few days. This either spontaneous or potentially DMSO-induced in vitro alteration was studied with a series of biological parameters, including conventional morphological and cytochemical analysis. Cytocentrifuge smears were prepared immediately after thawing (day 0) and again after 1, 2, 4, 6, and 8 days of culture. During this period, cell viability was always >95%.

On day 0, >95% of cytocentrifuged cells were undifferentiated blasts. This leukemic population appeared relatively homogeneous (maximal size was two times greater than that of a small resting lymphocyte) with a high nuclear-cytoplasmic (NC) ratio (Table 2). Cells did not contain granules and were not stained by Sudan black B or naphtyl butyrate esterase. No mitoses were seen in 10,000 cells examined. After 24 hours of culture, there were no major morphological changes. However, a slight decrease in N/C ratio and the emergence of granules in 10% to 15% of the cells was noted. Between day 1 and day 2 there was only a slight increase in the size of a fraction of the cells. Morphological transformation became evident on day 4 when 20% to 25% of the cells were granular. In addition, ~10% to 15% had a monocytoid aspect. On a representative smear, 23 mitoses per 1,000 cells were seen, suggesting a high degree of proliferation. After eight days of culture as much as 60% of the cells were granular and 30% to 40% were monocytoid. Less than 10% of cells had an undifferentiated blastic aspect; these cells were larger than their day 0 counterparts. The most differentiated myeloid cells appeared as metamyelocytes, although their morphology was abnormal because of an unusually large size and a maturation asynchronism between nucleus and cytoplasm. The onset of cytochemical markers was delayed and incomplete, suggesting enzymatic defects in the leukemic cells. In summary, morphological analysis indicated that a large fraction of the tumor cells underwent an in vitro activation process leading to proliferation and/or differentiation.

Thymidine incorporation and cell cycle analysis. Morphological analysis suggested that a fraction of the tumor cell entered S phase and subsequently proliferated. Thymidine incorporation was therefore investigated to analyze the kinetics of proliferation. Blast cells thawed on day 0 were cultured in triplicate. The first triplicate was pulsed immediately after thawing and harvested following 24 hours of culture. At that time, the second triplicate was pulsed and was harvested the next day. This procedure was repeated from day 0 to day 7. Prior to harvest, cultured cells were counted to determine cell concentration in the wells. Results of a representative experiment are shown in Fig. 1. Between day 0 and day 1, thymidine incorporation was at a background level of ~2,500 cpm. Subsequently, thymidine uptake rose progressively to peak on day 7 at ~50,000 cpm. Cell concentration in the cultures was stable for four days and then peaked on day 7 at 8×10^5/mL, whereas the blasts were initially seeded at 3×10^5/mL on day 0, indicating that a fraction of the cultured cells had strong proliferative capacity. During the first 24 hours of culture, thymidine uptake was very low, suggesting that most of the fresh leukemic blasts occurred in the GO/G1 phase of the cell cycle.

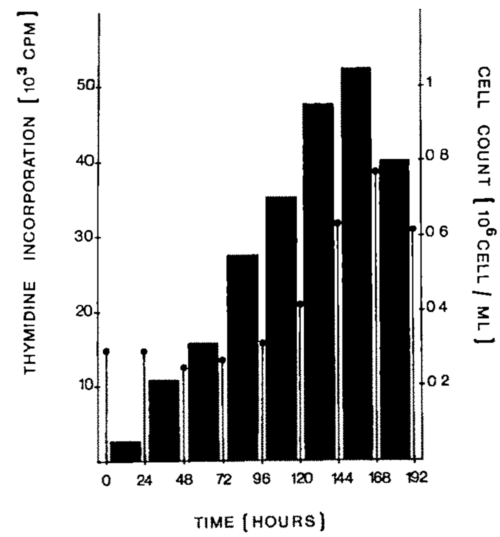

Fig 1. Tritiated thymidine uptake and cell concentration in leukemic blast cultures. (▮) Tritiated thymidine incorporation between time indicated on the left and time indicated on the right. For example, the first bar on left indicates thymidine uptake during first 24 hours of culture. (●) Cell concentration in culture at time indicated below.

To confirm this latter point, cells were treated immediately after thawing with ethidium bromide, which binds to double-stranded RNA as well as to DNA. Use of this reagent makes it possible to delineate the successive phases of the cell cycle from the resting GO stage (low RNA content and 2C DNA), through G1 (increased RNA content) and S/G2/M (DNA synthesis with >2C DNA content). Ethidium bromide staining suggested that most peripheral blood fresh blasts were in GO phase since their RNA and DNA content was not higher that that of control resting peripheral blood lymphocytes from a normal individual. Moreover, there was only a minimal increase ($\leq$5%) in fluorescent blast cells after 24 hours of culture. In contrast, after two days, ~20% of the cells were stongly fluorescent which, together with the

NK activity of allogeneic PBMCs against fresh and cultured leukemic cells. The NK activity of PBMCs and of large granular lymphocytes (LGL) (enriched or deprived fractions) was tested against fresh and cultured leukemia cells Effector cells were used either unstimulated or after an 18-hour treatment with recombinant IL 2. They were washed two times before being tested against chromium-labeled leukemia cells in a conventional four-hour assay. To standardize the experiment, blasts were harvested from bulk cultures on days 1 (24 hours of culture), 2, 4, 6, and 8 and were immediately frozen. Cryopreserved cells were then thawed simultaneously to perform the assays. Control experiments indicated that cryopreservation of the blasts at various times did not alter susceptibility to NK mediated lysis (data not shown).

Table 3 shows a representative experiment performed using peripheral blood from three normal donors known to have a relatively strong spontaneous lytic activity towards conventional NK target cell lines such as K562 or JM. Cytotoxicity of high-density lymphocytes (eg, small resting lymphocytes) is not presented in Table 3 because it was always at background levels (≤4%), even after treatment with IL2 PBMC and LGL-enriched fractions from all donors had no measurable activity against D0 (uncultured) leukemia cells. After rIL2 treatment, minimal cytotoxicity (6%) was observed only with LGL fraction from donor 3. In contrast, IL2 activated peripheral blood cells from the three donors displayed significant cytotoxicity against the cultured blasts. As expected, the strongest lytic activities were found in the LGL-enriched fractions which are known to contain the great majority of NK effector cells.[13] NK susceptibility was acquired very early during the course of the leukemia cell cultures as evidenced by the high degree of cytoxicity measured against D1 chromium-labeled blasts (≤34 percent specific cytotoxicity in donor 3). Subsequently decreasing but maintained cytoxicity was measured against D2, D4, and D6 leukemic cells.

Cytotoxicity of NK clones against fresh and cultured leukemic cells. The above experiments suggested that in vitro alteration of leukemic blasts was accompanied by an increased susceptibility to NK activity, particularly following IL2 treatment of effector cells. To study this phenomenon further, a series of human NK clones were used as effector cells in the same experimental system. These NK-cloned cell lines are monoclonal populations of IL2-dependent activated NK cells, which have been initially selected because of their non-MHC–restricted lytic capacity toward a series of tumor cells, including K562.

Table 4 shows that the NK clones used here either did not kill uncultured blasts (JT3, JT9, TRC48, or 49) or displayed a low level of cytotoxicity against these cells (TRC12, 50). However, each cloned cell line except JT3 was strongly lytic against the cultured blasts. Note that under these experimental conditions, cytotoxicity of all clones, including JT3, was >60% against K562 cells (Table 1B). Correlating results obtained with IL2 stimulated peripheral blood cells, maximum cytotoxicity displayed by the clones was reached as early as day 1. For example, using TC12 as effector cells, specific cytotoxicity rose from 8% on day 0 to 54% on day 1. Subsequently, decreasing but maintained cytotoxicity was observed against blasts cultured for 2, 4, 6, and 8 days.

Cold target inhibition experiments. To investigate why resistant fresh blasts became susceptible to most NK cells tested following a short-term culture, cold target inhibition experiments were performed. Cytotoxicity of TC12 and TC50 cells was tested against chromium-labeled D2 blasts in the presence of medium or increasing numbers of either cold D0 blasts, cold D2 blasts or cold K562 cells. Results shown in Fig 2 were similar for clones TC12 and TC50, which both displayed low levels of cytotoxicity against fresh blasts (Table 4). It was found that D0 leukemic cells were poor cold target competitors; at a 20/1 cold/hot target ratio, inhibition was 28% and 22% using TC12 and TC50 cloned effector cells, respectively. In contrast addition of either cold D2 blasts or K562 cells induced a strong inhibition of measured cytotoxicity. For example, at 20/L cold/hot target ratio, using TC12 as effector cells, 72% and 88% inhibition were obtained with D2 blasts and K562 cells, respectively. These

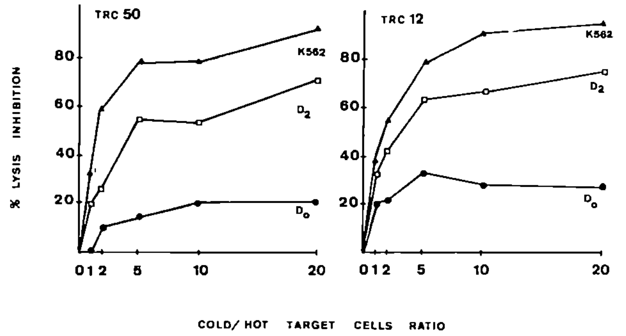

Fig 2. Cold target inhibition assays. Cytotoxicity was measured following four-hour assays. First TC50 and TC12 cloned cells were plated. Subsequently, either cold D0 blasts, D2 blasts, or K562 cells were seeded at a cold/hot ratio as indicated. Finally, radiolabeled D2 blasts were added at 5,000 cells per well. Experiments were performed in triplicate cultures. SD for each point was <12%. Effector/radiolabeled target ratio was 5:1.

results suggested a binding defect between cloned NK cells and fresh leukemic blasts.

Receptors involved in cytotoxic reactions against leukemic blasts. In previous studies, we demonstrated that a surface structure expressed on lymphoid cells within 24 hours following mitogen activation is likely to represent a target antigen for a series of NKTa+ cloned NK cell lines, including JT9.[7,14] It was of interest to investigate the expression of this molecule, termed TNKtar, on the membrane of either fresh or short-term-cultured leukemic blasts. Indirect immunofluorescence assays were performed and followed by cytofluorometric analysis It was found (Fig 3) that TNKtar was either expressed with very low density or was absent on D0 blasts; however, after 24 hours of culture, anti-TNKtar strongly reacted with most of the leukemic cells. This expression was then maintained during the eight days of culture (Fig 3) Because TNKtar surface expression correlated with acquired susceptibility to NK clones including JT9, blocking experiments were conducted. The cytotoxicity of JT9 cells was tested against D0, 1, 2, 4, and 6 blasts. JT9 cells and leukemic blasts were treated with anti-NKTa (used here as a positive control) and anti-TNKtar,[14] respectively. NKTa and TNKtar have been previously shown to recognize at the effector[7] and target cell level[14] receptors involved in the cytotoxic reactions mediated by JT9 against conventional NK target hematopoietic cell lines. JT9 cells were incubated with either medium or a saturating concentration of anti-NKTa for three hours at 37 °C. Subsequently, chromium-labeled blasts were added. Reciprocally labeled leukemic cells were incubated with saturating concentration of anti-TNKtar for one hour at 37 °C prior to addition of JT9 cells. As shown in Table 5, it was found that anti-NKTa and anti-TNKtar were both able to block these cytotoxic reactions significantly. For example, against D1 blasts, inhibition of lysis induced by anti-NKTa was 66%; anti-TNKtar treatment resulted in a 56% inhibition.

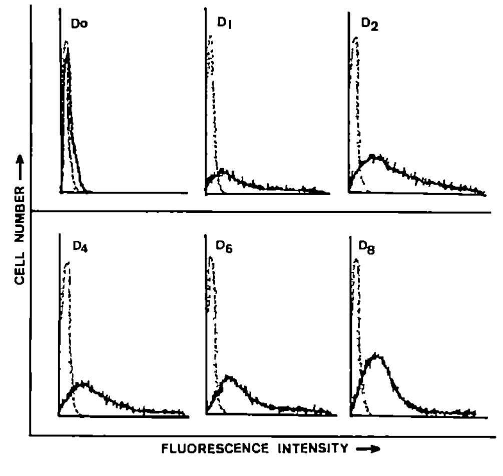

Fig 3. Surface expression of TNKtar antigen during in vitro cultures. Surface expression of TNKtar on leukemic cells was measured using indirect immunofluorescence assays followed by cytofluorometric analysis on a FACS 440. The diagrams represent number of cells (ordinate) v intensity of fluorescence (abscissa) expressed on an arithmetic scale; (· · ·) background fluorescence obtained with the unreactive anticlonotypic NKTa monoclonal antibody; (——) reactivity of anti-TNKtar. The percentage of TNKtar+ cells in the culture was evaluated as follows: day 0, 4%; day 1, 68%; day 2, 66%; day 4, 75%; day 6, 70%; day 7, 56%.

JM, a long-term-cultured cell line derived from a T cell leukemia, was used as a control. Treatment of JT9 cells with anti-NKTa resulted in a strong blockade of the cytolytic reaction against JM, whereas treatment of this target cell line with anti-TNKtar resulted in a partial but significant blockade, as previously reported.[14] Antibodies directed at unrelated structures, such as T8 on the effector cells or Ia on the target cells, have no blocking effect at all in this experimental system (data not shown).

DISCUSSION

In this study, we have examined in vitro alteration of undifferentiated circulating leukemic blasts obtained from a patient with acute myeloid leukemia Susceptibility to NK activity was investigated in parallel. Thymidine uptake was found to be very low in the fresh blasts. After 24 hours of culture, increasing fractions of leukemic cells began to enter S phase A week later, >80% of the cells had undergone differentiation, as evidenced by morphological criteria. Indeed, on day 8, <10% of the cells appeared as undifferentiated blasts, whereas 50% to 60% were granular, and 30% to 40% had a monocytoid aspect. During the first day of culture, leukemic cells which were resistant immediately after thawing became susceptible to lysis by IL2-activated NK cells. Simultaneously, membrane modifications took place since the TNKtar antigen, not present on day 0, was strongly expressed on the surface of the blasts by day 1

Moreover using the JT9 cloned cell line, we demonstrated that anti-TNKtar was able to block significantly the cytotoxic reaction against the cultured leukemic cells.

NK activity is operationally defined as the capacity displayed by a population of lymphocytes to destroy without apparent preimmunization a series of activated cells such as myeloid progenitors,[15] viral-transformed cells and, of course, tumor cells.[16] This spontaneous lytic activity mediated by NK cells is enhanced following short-term incubation with IL2.[17] Using a given target cell, biological mechanisms responsible for transformation from resistant to susceptible phenotype are presently unknown Therefore, the preferential susceptiblity of activated cells to natural killing is not well understood. In this respect, experiments designed to investigate the role of target cell activation in NK susceptibility cannot be performed with permanently growing hematopoietic cell lines (ie, K562).

We have had the opportunity to study fresh leukemic blasts which, in culture, undergo a rapid activation leading to subsequent proliferation and/or differentiation. The triggering stimulus responsible for these in vitro alterations may have been DMSO, since blasts were cryopreserved prior to being studied. It is also conceivable that circulating blasts were undifferentiated because of in vivo suppression mechanisms. Fresh leukemic cells were found to be resistant to both resting and IL2-enhanced natural killing. In contrast, the blasts became clearly susceptible to this latter type of cytotoxicity during in vitro culture. However, susceptibility to IL2-activated NK cells was acquired prior to an increase in DNA synthesis and subsequent proliferation, and before further steps of morphological differentation were reached. Consequently it is evident that, in the present experimental system, acquisition of susceptibility did not correlate with a stage of further differentiation but with an early step of cell activation that would eventually lead to it. Furthermore, there was a positive correlation between susceptibility and early surface expression on target blasts of TNKtar antigen.[14]

TNKtar is a 40 to 80-kd heterodimeric structure previously shown to be identical to 4F2.[18,19] It is found at various densities on all human cultured cell lines of hematopoietic and extra hematopoietic origin that have been tested thus far. This molecule is present with a very low density on normal lymphoid cells but is strongly expressed within 24 hours after cell activation triggered, for example, by mitogens. We have shown that TNKtar also represents an activation-dependent surface antigen on myeloid cells that had not been previously established. TNKtar was identified in earlier studies[14] as one target structure "seen" on cultured hematopoietic cell line membranes by a series of NK clones including JT9, which has been described in detail.[6,7,14] JT9 cells have a mature T cell phenotype coexpressing T1, T3, T8, T11, and T12 antigens. Moreover, they possess a clonotypic receptor termed NKTa[7] which is functionally and biochemically analogous to Ti molecules.[20,21] However, as opposed to conventional CTL, JT9 cells express NKH1A, like all NK cells,[12] and kill genetically unrelated hematopoietic tumor cell lines, including K562, in an MHC-independent fashion. Data presented here further substantiate the hypothesis that TNKtar functions as a receptor recognized on target cells by JT9 cloned lymphocytes, since anti-TNKtar blocked their cytotoxic activity against the present leukemic blasts which have not been cultured long-term. It is perhaps more important, that an unique positive correlation could be established, using a population of fresh tumor cells, between acquisition of susceptibility to JT9 and concomitant surface expression of TNKtar. It is therefore suggested that, during the process of target cell activation, TNKtar expression may represent a necessary signal for recognition and subsequent lysis.

As shown in these studies, LGL fractions and all NK clones tested capable of killing the leukemic blasts reached a maximal level of cytotoxicity within 24 hours of culture. This observation is of interest in light of the heterogeneity of human NK cells. Indeed, it is now well established that natural killing is mediated by distinct and probably multiple populations of cytotoxic lymphocytes.[22-27] The development of human NK clones has helped[4-7] to demonstrate this heterogeneity and, more important, has helped to dissect it because monoclonal populations of cells can be analyzed by this approach. As mentioned, it was established by studying NK clones that certain $[T3/Ti]^+$ cells express NK-associated antigens such as NKH1A and behave functionally as NK cells. However, it is clear that they represent a very minor population within NK active lymphocytes which, in the great majority are T3− NKH1A+.[12] Except for JT9, all NK clones used in these studies are T3− NKH1A+ and partially reflect the heterogeneity of circulating NK cells. Indeed, they display four distinct NK-associated phenotypes characterized by a limited series of Mabs. Moreover, they may express major differences in lytic repertoire[6] although they cannot be distinguished phenotypically. For example, JT3 and TC59 cells are both T3−, T4−, T8−, T11+, NKH1A+, and NKH2+ (Table 1A), and they kill K562, and JM cell lines (Table 1B). However, JT3 has very little cytotoxicity against leukemic blasts, whereas TC59 is strongly active against these latter tumor cells (Table 4).

The structure(s) recognized on target cell membranes by individual populations of T3−, NKH1A+, NK active lymphocytes is unknown. It is certainly not TNKtar antigen (or a close epitope) because the corresponding antibody does not block cytotoxic reactions mediated by a number of representative clones. Yet it remains to be determined whether target structure(s) (eg, TNKtar) of $[T3/Ti]^+$, $NKH1A^+$ cells such as JT9, and target structure(s) of $T3^-$ $NKH1A^+$ cells are either distant regions of the same molecule or are distinct antigens linked to cell activation or, alternatively, totally unrelated structures. The present data suggest that the latter hypothesis is unlikely. We found that in spite of the phenotypic and functional heterogeneity of NK cells, LGL fractions and all active clones became lytic at the same time during in vitro alteration of the leukemic cells. Meanwhile, cold target inhibition experiments indicated that lack of initial cytotoxicity by individual populations of T3−, NKH1A+ cells was probably due to a binding defect. These results strongly suggest that target structure(s) for at least a fraction of T3−, NKH1A+ NK active lymphocytes are expressed very early and with kinetics similar to those of

TNKtar in the process of target cell activation. Consequently, analysis of the present experimental system supports the view that the search for currently undefined NK target structure(s) should further focus on the identification and characterization of early activation antigens.

Multiple studies have pointed out that NK cells may play an important role in host defense against tumors.[16] The data presented here suggest that a better understanding of NK target cell interaction mechanisms should help to delineate strategies of immunomanipulation. For example, in this patient, both activation of circulating blasts by an appropriate drug and enhancement of NK cell cytotoxicity by IL2 would have been required for the design of a potentially beneficial adjuvant therapy.

ACKNOWLEDGMENT

The authors would like to thank Mrs M Y Guillard and E Leclercq for excellent technical assistance and Mrs D. Rivierre for skillfull assistance in the preparation of this manuscript.

Diversity of Human γ-Globin Gene Loci Including a Quadruplicated Arrangement

By Shunichi Shimasaki and Iwao Iuchi

A quadruplicated γ-globin gene as a (5′-$^G\gamma$-γ-γ-$^A\gamma$-3′) was detected in an adult Chinese during a survey designed to detect $^G\gamma$- and $^A\gamma$-globin genes in Japanese. Five triplicated (-$^G\gamma$-γ-$^A\gamma$-) and two single (-γ-) haplotypes were also detected in 103 healthy adult Japanese. All of the unusual chromosomes appeared to reflect an unequal but homologous crossover between $^G\gamma$- and $^A\gamma$-globin genes. A new *Bgl* II polymorphic site located around the 3′ terminal region of the $^G\gamma$-globin gene was also discovered.

© 1986 by Grune & Stratton, Inc.

THE DUPLICATED human fetal globin genes encode different forms of γ-chains designated as $^G\gamma$ and $^A\gamma$. The two genes originate by duplication of five kilobases (kb) of DNA, either through a simple unequal recombination of two small preexisting repetitive elements or through a more complex series of events not requiring any preexisting repeats.[1]

Based on a comparison of the DNA sequences of the two γ-globin genes, the occurrence of interchromosomally unequal but homologous crossovers between $^G\gamma$- and $^A\gamma$-globin genes (gene conversion) has been strongly suggested.[1,2] An unusual arrangement of the γ-globin gene locus in a chromosome has also been reported in some racial groups,[3,4] as expressed in a haploidy formula of -γ-γ-γ-/ or -γ-/.

We examined the arrangement of γ-globin genes to learn the frequency of intergenic crossover in Japanese. The results of that survey are reported, with special emphasis on the discovery of a quadruplicated γ-globin gene haplotype (four γ-globin gene loci on one chromosome)

MATERIALS AND METHODS

Routine hematologic studies were carried out by standard methods [5] Conventional methods were used for hemolysate preparation and fetal hemoglobin (Hb F) determination.[6] Blot hybridization studies were performed with DNAs of 104 healthy unrelated adults (103 Japanese and one Chinese)

A DNA sample of high mol wt was isolated from leukocytes collected from 10 mL of venous blood by standard methods [7] Four micrograms of each sample were digested with 20 U of *Bgl* II for five hours under conditions recommended by the manufacturer (Takara Shuzo Co, Ltd, Kyoto, Japan). Cleaved DNA fragments were precipitated with ethanol and redissolved in 30 μL of TE (10 mmol/L of Tris-HCl, 1 mmol/L of EDTA, pH 8 0) buffer. The DNA digest was electrophoresed on a 0 6% agarose gel (pH 8.0) and transferred onto a nylon membrane (Zeta-Probe, Bio-Rad, Richmond, Calif) by Southern blotting method.[8]

The DNA fragments on the membrane were hybridized to a mixture of three radioactive probes: (a) a 3.4-kb *Hind* III fragment containing the $^A\gamma$-globin gene; (b) a 2 3-kb *Pst* I fragment containing the δ-globin gene; and (c) a 3.8-kb *Pst* I-*Bgl* II fragment containing the β-globin gene. Each of the DNA probes was derived separately from recombinant plasmids pγ 3.4,[9] *Pst* δ (pHδ_1)[9] or *Pst* β[10] isolated individually from transformed *E coli* HB 101 under P2-EK1 containment conditions in accordance with the guidelines of the Ministry of Education, Science and Culture of Japan.

The probe fragments were nick-translated[11] in the presence of α-^{32}P dCTP to convert them into a radioactive form. Their specific activity was in a range of 1 to 3×10^8 dpm/μg After hybridization, the nylon membranes were washed stringently, dried, and exposed to x-ray film at −70 °C for 15 hours according to the protocols described by Goossens and Kan.[12]

DNA samples that showed an abnormal pattern on autoradiograms were further digested by other restriction endonucleases including *Bcl* I, *Xmn* I, *Pst* I, *Xba* I, *Bam* HI, and *Eco* RI, followed by the same analyses except for hybridization to an individual probe.

RESULTS

Bgl II cleaves human DNA to produce the linked γ-globin gene ($^G\gamma$ and $^A\gamma$) loci and each of the δ-globin and β-globin gene loci. Autoradiograms obtained by a mixture probe demonstrated clear bands certifying complete DNA digestion with *Bgl* II and providing an accurate estimation of the DNA fragment sizes (Fig 1).

The autoradiograms of 104 individuals obtained by *Bgl* II digestion and use of the mixture of probes revealed 95 instances carrying the DNA bands of 13, 8.2, and 5.0 kb with approximately equal intensity on scanning. They could be accordingly classified into the most common genotype (group N in Fig 1). The other nine DNA samples, however, showed a clear but fainter 13-kb band than did those of 8.2 and 5.0 kb (groups A, B, C, and D in Fig 1). In addition, seven of these nine samples showed an extra restriction fragment. DNA samples from these nine individuals were accordingly classified into four groups: A (5 cases), B (one case), C (2 cases), and D (one case) based on the band pattern

In order to identify these extra bands, hybridization to each probe was carried out individually; only the γ-globin specific probe hybridized to each of the extra bands (Fig 2). Moreover, additional extra bands (8.1 kb) were observed in the samples of group C which had not been recognized as containing an extra band when hybridized to the mixture of probe.

The sizes of the extra bands were estimated to be 18, 23, and 8.1 kb in groups A, B, and C, respectively, and 10 and 3.2 kb in group D. It was evident that the 8.1-kb band in group C was superimposed on the 8.2-Kb *Bgl* II band derived from the δ-globin gene by hybridization to the mixture of probes.

The nine DNA samples were digested with *Bcl* I. Autoradiograms detected the 20-kb fragment commonly seen due to digestion outside the linked γ-globin gene loci in each and an extra fragment of varied size in all samples except for the

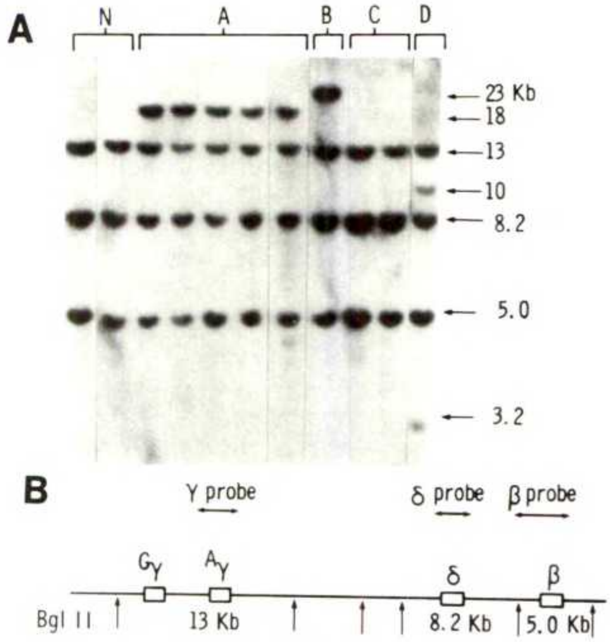

Fig 1. (A) Autoradiogram of *Bgl* II digestion patterns. Probe: $\gamma + \delta + \beta$; n, usual 95 individuals. A, B, C, D are groups with an unusual band pattern. (B) *Bgl* II restriction sites in a usual non-α-globin gene cluster.

individual of group D (Fig 2). The difference in the size of these extra fragments from the normal 20-kb fragment was the same as the difference between the extra bands observed with *Bgl* II digestion and the usual 13-kb *Bgl* II fragment. It was consequently considered that the 13-kb *Bgl* II fragment contained: (a) an additional 5-kb DNA in group A; (b) an additional 10-kb DNA in group B; (c) a deletion of 5-kb DNA in group C; and (d) an additional *Bgl* II restriction site dividing the usual 13-kb fragment into 10-kb and 3.2-kb fragments in group D. This phenomenon was further confirmed by digestion with *Xmn* I, which cleaves human DNA to produce the linked γ-globin gene as shown in Fig 3. When the genomic DNA of group N was digested with *Xmn* I and hybridized to a γ probe, three types of fragment patterns were observed (Table 1) in accordance with a polymorphic *Xmn* I site at 157 to 166 base pairs (bp) 5′ to the Cap site of the ${}^{G}\gamma$-globin gene (Fig 3).[13] In groups A, B, and C, extra bands with an additive or a reductive size of 5 kb or 10 kb as compared to the common bands were observed as seen in *Bgl* II digestion (Table 1).

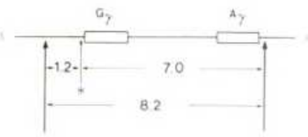

Fig 3. *Xmn* I restriction sites around ${}^{G}\gamma$- and ${}^{A}\gamma$-globin genes. Asterisk denotes the *Xmn* I polymorphic site. Sizes in kilobases.

The DNA samples were then digested with *Pst* I, which cleaves at the site of the codon corresponding to the 136th amino acid of the ${}^{A}\gamma$-globin chain (third exon) but not at the same position in the ${}^{G}\gamma$-globin gene. The autoradiograms obtained with a γ probe revealed the three normal bands (Fig 4). The relative intensities of the intergenic 4.9-kb fragment between ${}^{G}\gamma$- and ${}^{A}\gamma$-globin gene was compared to the two bands of 4.0 kb and 2.8 kb derived from the upstream region of the ${}^{G}\gamma$-gene and the downstream region of ${}^{A}\gamma$-gene, respectively. The ratios were higher in groups A and B and lower in group C than were those of the common group. Namely, the relative intensities of the 4.9-kb band to 4.0-kb band were 1.4, 1.8, 2.5, 0.8, and 1.4 for groups N, A, B, C, and D, respectively.

Xba I, *Bam* HI, and *Eco* RI were also used to characterize these unusual DNAs. All of the intergenic DNA fragments shown with arrows in Table 2 demonstrated the same tendency as did *Pst* I digestion. For example, the *Xba* I digestion showed the relative intensities of the intergenic 4.9–7.5-Kb fragment as 1.9, 2.5, 3.3, 1.4, and 1.9 for groups N, A, B, C and D, respectively. Restriction endonuclease maps around the fetal globin genes of these unusual chromosomes were established by these findings, as in Fig 5.

Two different-sized fragments of group B observed by the *Bgl* II, *Bcl* I, and *Xmn* I digestion were thought to come from the heterozygosity of the γ-globin gene cluster. The individual in group B was therefore considered to be heterozygous for the quadruplicated γ-globin gene rather than homozygous for a chromosome with three γ-globin genes. The individuals of groups A and C were heterozygous for triplicated and single γ-globin genes, respectively. The frequen-

cies of the triplicated γ-globin haplotype and the single one in this survey were 0.024 and 0.010, respectively.

The nine individuals of groups A, B, C, and D showed no hematologic abnormalities or evidence of hemolysis (RBC, PCV, Hb, MCV, MCHC, MCH, reticulocyte count, and serum bilirubin), and their Hb F of 0.2% to 0.4% were within the normal range.

DISCUSSION

A high degree of homology between the $^{G}\gamma$- and $^{A}\gamma$-globin genes extends from about 500 bp 5′ to the Cap site to a region of simple base sequence within the large intervening sequence (IVS-2).[1] This simple base sequence region seems the most likely site for an interchromosomally unequal but homologous crossover. The crossover mechanism between the $^{G}\gamma$- and the $^{A}\gamma$-globin gene may be shown as in Fig 6, based on a general model for genetic recombination proposed by Meselson and Radding.[13,14] When a branch migration from a cross-bridge site is short, and the strand cleavage occurs within the gene, a new single hybrid gene represented as -$^{G}\gamma^{A}\gamma$- is generated. When the branch migration extends upstream beyond the gene, the single γ-globin gene is an intact $^{A}\gamma$-gene. In the case of the triplicated γ-globin gene chromosome, on the other hand, the central gene generated by the crossover may be -$^{G}\gamma$- or -$^{A}\gamma^{G}\gamma$- depending on subsequent DNA replication or mismatch repair in the heteroduplex region. This haplotype is therefore expressed as 5′-$^{G}\gamma$-γ-$^{A}\gamma$-3′ without defining the central γ-globin gene.

The region of the crossover on the eight unusual chromosomes we studied was inferred from the *Pst* I and *Xmn* I analysis. The *Pst* I sites, specific for $^{A}\gamma$-genes, were not present in all of the inner genes of the triplicated and the quadruplicated γ-globin gene chromosomes, but analyses of the single γ-globin gene chromosomes clearly showed this cleavage site. These results suggest that all the crossover events occurred upstream from the *Pst* I site in the 3rd exon, of the $^{A}\gamma$ gene.

In the *Xmn* I analysis, the appearance of the extra fragments of 13 and 18 kb in groups A and B, respectively, suggests that the crossover occcurred within the normal 8.2-kb *Xmn* I fragment. The left *Xmn* I site defining the 8.2-kb fragment in Fig 3 is at 1.3 Kb upstream from the Cap site of the $^{G}\gamma$-globin gene. The crossover region of groups A and B, therefore, occurred between the *Xmn* I site 1.3 kb 5′ to

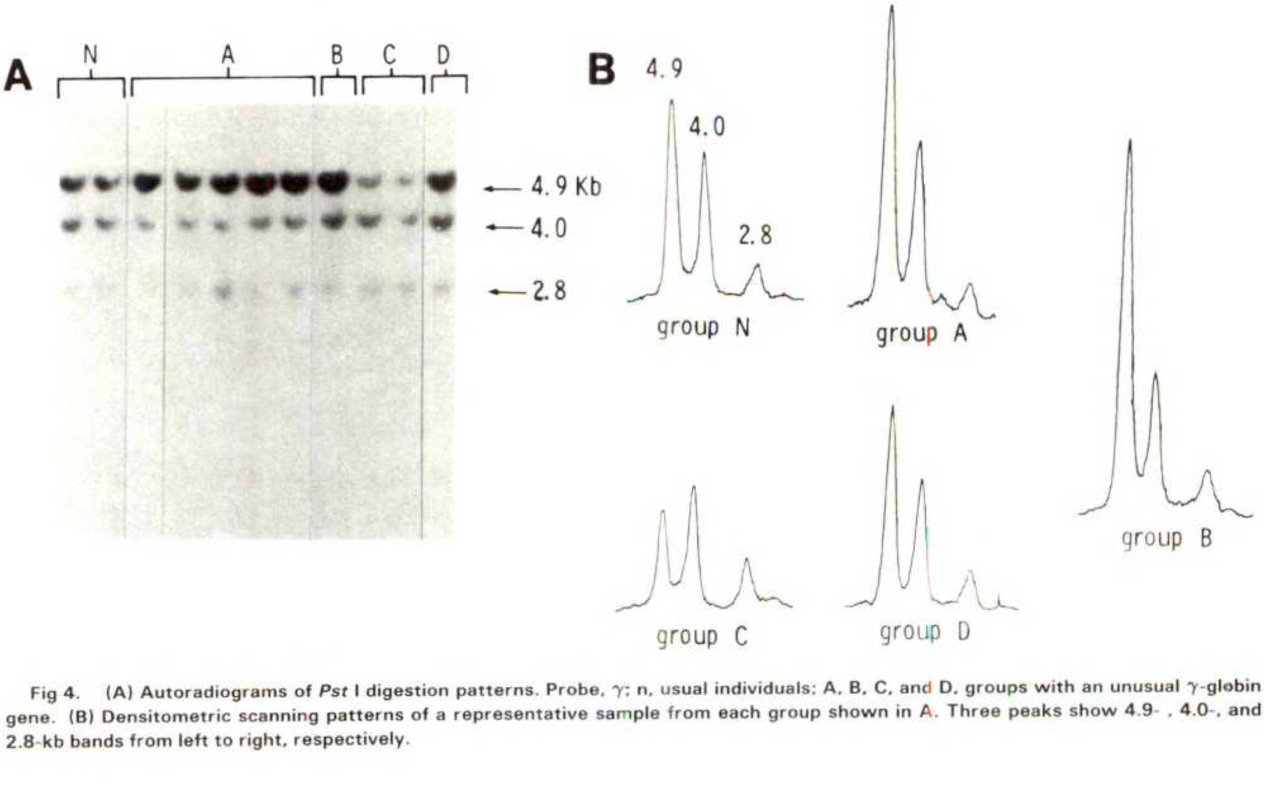

Fig 4. (A) Autoradiograms of *Pst* I digestion patterns. Probe, γ; n, usual individuals; A, B, C, and D, groups with an unusual γ-globin gene. (B) Densitometric scanning patterns of a representative sample from each group shown in A. Three peaks show 4.9- , 4.0-, and 2.8-kb bands from left to right, respectively.

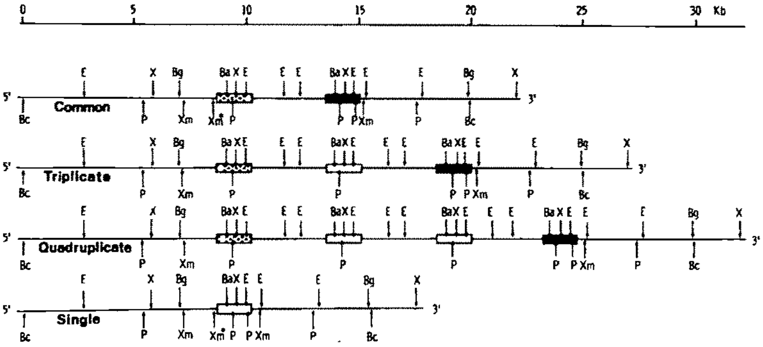

Fig 5. Gene arrangement and restriction endonuclease maps of usual and unusual γ-globin gene clusters. Asterisk represents *Xmn* I polymorphic restriction site. Stippled and hatched rectangular boxes are $^G\gamma$- and $^A\gamma$-globin gene, respectively. Open rectangular boxes are γ-globin genes generated by cross-over. Ba, *Bam* HI; Bc, *Bcl* I; Bg, *Bgl* II; E, *Eco* RI; P, *Pst I*; X, *Xba* I; Xm, *Xmn* I.

the Cap site of the $^G\gamma$ gene and the *Pst* I site in the 3rd exon of the $^A\gamma$ gene.

Formation of these hybrid chromosomes by interchromosomal crossovers occurs within the region proposed by Shen et al.[1] The quadruplicated γ-globin gene haplotype may have arisen through an unequal but homologous crossover between the triplicated and the usual duplicated haplotypes or between two triplicated haplotypes. It is accordingly represented as 5′-$^G\gamma$-γ-γ-$^A\gamma$-3′.

The process of unequal but homologous crossover produces an equal number of chromosomes with a triplicated γ-globin gene locus and a single one. However, the frequency of the triplicated γ-globin gene chromosome was twice as great as that of the single γ-globin gene chromosome in this survey. It is unlikely to suppose that a single γ-globin gene haplotype confers a serious selective disadvantage; two newborns who were homozygous for a single γ-globin gene have been reported without severe γ-thalassemia.[15] The number of γ-globin gene loci does not affect Hb F production in adults since the Hb F levels were within normal limits.

This article provides a description of a *Bgl* II polymorphic restriction site near the globin genes. One individual in group D demonstrated a site that split the usual 13-kb fragment containing the $^G\gamma$- and $^A\gamma$-globin genes into 10-kb and 3.2-kb fragments. The probe used in this hybridization was an $^A\gamma$ *Hind* III 3.4-kb fragment which could also hybridize to the homologous $^G\gamma$-gene sequence. If the new polymorphic *Bgl* II site is located 3.2 kb 3′ to the leftward *Bgl* II site of the 13-kb fragment shown in Fig 1, it would be observed on the autoradiogram. On the other hand, if the 3.2-kb fragment derived from the opposite end of the 13-kb fragment, it would not be expected to hybridize to the γ probe. The observed 3.2-kb fragment was, therefore, formed by a new *Bgl* II site near the 3′ terminal region of the $^G\gamma$-globin gene.

ACKNOWLEDGMENT

The authors are deeply indebted to Emeritus Professor Yasuyuki Takagi and to Drs Yasuyuki Fukumaki and Akinori Kumura, Department of Biochemistry, Kyushu University School of Medicine, for their kind instruction in globin gene analysis and a gift of recombinant probes, pγ 3.4 and *Pst β*. Appreciation is extended to Professor Tom Maniatis, Department of Biochemistry and Molecular Biology, Harvard University, for a gift of recombinant probe, *Pst* δ (pHδ$_1$), and to Miss Yuko Nishina for her technical assistance.

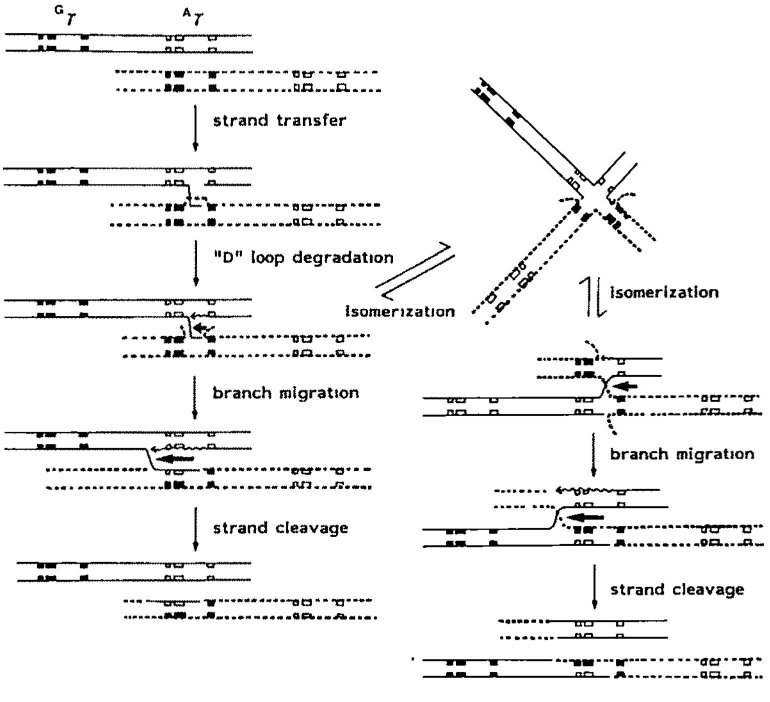

Fig 6. Possible recombination model between $^G\gamma$-globin and $^A\gamma$-globin genes. The black and white boxes represent the globin coding region. The wave lines with an arrow denote a replicating DNA strand.

Effect of Acidic and Basic Isoferritins on In Vitro Growth of Human Granulocyte-Monocyte Progenitors

By Laura Dezza, Mario Cazzola, Wanda Piacibello, Paolo Arosio, Sonia Levi, and Massimo Aglietta

Acidic isoferritins have been previously found to be highly potent inhibitors of hematopoietic progenitors at concentrations of 10^{-16} to 10^{-18} mol/L, and it has been suggested that acidic isoferritin inhibitory activity plays a role in the regulation of normal hematopoiesis and also in the pathogenesis of leukemia. To characterize the ferritin species that affect the in vitro growth of human colony-forming unit–granulocyte-macrophage (CFU-GM), we tested different preparations of basic (L-subunit–rich) and acidic (H-subunit-rich) isoferritins. Three preparations of human liver (basic) ferritin did not show any effects on CFU-GM growth at concentrations up to 10^{-9} mol/L, irrespective of the degree of glycosylation. Acidic isoferritins were purified both from HeLa cells and human heart. HeLa cell ferritin did not affect in vitro colony formation. One of two preparations of human heart ferritin, containing 5% glycosylated ferritin, showed a mean inhibition of 26% ± 8% of the control at 10^{-9} mol/L ($P < .02$), whereas the other preparation, which contained no glycosylated ferritin, did not show any effect of CFU-GM growth. A preparation enriched for glycosylated acidic isoferritins from human heart was found to produce a mean inhibition of 32% ± 11% of the control at 10^{-9} mol/L ($P < .01$), whereas another one was ineffective. A significant part of the inhibitory activity was removed by preincubation with the monoclonal antibody 2A4 directed against human heart ferritin. The present findings indicate that basic isoferritins, ie, the predominant ferritin type in human blood, have no effect on the growth of human CFU-GM, and this is in keeping with indirect clinical evidence. Inhibition of colony formation may be obtained by some preparations of acidic isoferritins that are rich in H subunits and bind to concanavalin A. The mechanism(s) responsible for this are not clear, but the effective concentrations are higher than those found in human blood both under normal conditions and in leukemia. At present, the physiologic significance of the observed inhibitory activity is uncertain.

FERRITIN is ubiquitous in all cells, and its major functions are iron storage and detoxification.[1,2] The structural and immunologic properties of this molecule vary from one tissue to another and are related not only to the iron status but also to other factors including cell differentiation and malignant transformation.[3,4] Multiple forms of ferritin occur in most cells, with all molecules consisting of 24 subunits arranged as hollow protein shells having an approximate molecular weight of 500,000.[3] These isoferritins are families of heteropolymers fashioned from different proportions of two distinct subunit classes, heavy (H) and light (L), with molecular weights of approximately 21,000 and 19,000, respectively.[3] The L-subunit–rich isoferritins are basic (high pI) and predominate in iron storage organs (liver and spleen) and plasma, whereas the H-subunit–rich isoferritins are acidic (low pI) and occur in tissues of low nonheme iron content (heart, erythroid cells, monocytes, lymphocytes) and in fetal and some malignant tissues. This model for tissue ferritin phenotypes based on two distinct subunit species has been validated by the demonstration that the two subunits are encoded by distinct messenger RNAs (mRNAs)[5] and recent evidence for the existence of at least two ferritin genes.[6–8] However, the matter could be more complex because a glycosylated G subunit (molecular weight about 23,000) has been isolated from human serum.[9] It is possible to evaluate basic and acidic isoferritins separately using immunoassays based on monospecific antibodies raised against L-subunit–rich and H-subunit–rich molecules.[10]

Although ferritin function is inextricably linked to iron metabolism,[11] there has been evidence of a role for ferritin in lymphocyte migration[12] and T cell function[13] as well as in the control of myelopoiesis. In fact, a leukemia-associated inhibitory activity (LIA) directed against human granulocyte-monocyte progenitors[14] was identified by Broxmeyer and his associates as acidic isoferritins.[15] Acidic isoferritin inhibitory activity (AIFIA) was later found in bone marrow and blood cells of normal donors,[16] and a specific role for monocyte-macrophage–derived acidic isoferritins as feedback regulators of hematopoietic progenitor cells was suggested.[16] However, this has been disputed because of certain inconsistencies with the present picture of human isoferritins.[17]

In this work, we have studied the effects of different isoferritins on the growth of cultured granulocyte-macrophage precursor cells and correlated these effects with biochemical and immunologic characteristics of the ferritin tested.

MATERIALS AND METHODS

Purification of human liver, heart, and HeLa cell ferritin. Eight ferritin preparations were made and coded as A, B, C, D, E, F, G, and H. The main characteristics of these isoferritins are reported in Table 1.

The procedure for purification of human liver ferritin (preparations A and B) was essentially the same as previously described in detail by Arosio et al.[18] It consisted of heat extraction at 75 °C, ammonium sulfate precipitation (60% saturation), precipitation at

Abbreviation: Con A, concanavalin A.

*Ferritin concentration was evaluated with immunoradiometric assays based on polyclonal antibodies against human liver ferritin and the monoclonal antibody 2A4 against human heart ferritin; each value was then expressed as a percentage of the total ferritin concentration

300,000 g for 90 minutes, gel filtration on a Sepharose 4B column, and crystallization with 5% cadmium sulfate.

Human heart (preparation D) and HeLa (preparation E) ferritins were purified by similar procedures except that the crystallization step was omitted and replaced with diethyl aminoethyl chromatography and preparative gel electrophoresis on a polyacrylamide gradient (10% to 30%) gel slab

Human heart preparation C was purified with a similar procedure except that the heated homogenate was passed through a column of Affi gel Blue (Bio-Rad Laboratories, Richmond, Calif); equilibrated in 20 mmol/L Tris-HCl, pH 7.4, and on a column of Con A–Sepharose (Pharmacia Fine Chemicals, Uppsala, Sweden); and the break-through peaks collected. For this preparation, the preparative gel electrophoresis step was omitted.

Isoferritin preparations were analyzed by means of isoelectrofocusing, sodium dodecyl sulfate (SDS) electrophoresis, and immunoblotting as previously described.[10,18,19] Preparations A, B, D, and E appeared pure by native and SDS gel electrophoretic analyses, whereas preparation C contained 5% contaminants. The ferritin protein concentration was determined by the method of Lowry et al [20]

Glycosylated ferritins were obtained by loading nonheated tissue homogenates (preparations F and H) or heated homogenates (preparation G) on a Con A–Sepharose column. After extensive washing, glycosylated proteins were eluted with 0.1 mol/L α-methyl glucoside. These preparations were concentrated either on an Amicon M 300 membrane (preparation F and H) (Amicon Corp, Danvers, Mass) or by precipitation at 300,000 g for 90 minutes (preparation G). The ferritin concentration was detected by immunoassays In ferritin preparations F and G, ferritin did not account for more than 5% of the total protein, whereas preparation H was somewhat more than 10% pure.

Monoclonal antibody to heart ferritin. The monoclonal antibody 2A4 against human heart ferritin was developed by Cavanna et al,[21] and its characteristics were reported by Arosio et al.[10]

Immunoassays for liver and heart ferritin. The two-site immunoradiometric assay for human liver ferritin was prepared as previously described.[22] The two-site immunoradiometric assay for heart ferritin was prepared as described by Cavanna et al[21] using the monoclonal antibody 2A4

Binding to Con A. This was determined as previously detailed.[10]

CFU-GM assay procedures Normal bone marrow was obtained from normal volunteers or from patients undergoing chest surgery for nonmalignant diseases. Bone marrow cells were collected in preservative-free heparin (50 to 100 U/mL) A quantity of 1×10^5 low-density bone marrow cells, separated as previously described,[23] were plated in a 1-mL mixture containing Iscove's modification of Dulbecco's medium (IMDM), 15% fetal bovine serum, 0.3% agar (Difco Laboratories, Detroit, Mich), and 10% conditioned medium from the 5637 cell line as a source of colony-stimulating activity (CSA) in the presence or absence of the various isoferritins. Sodium azide was removed from the isoferritin preparations by dialysis prior to the cultures. Preliminary studies showed that ferritin concentrations in the 5637-conditioned medium were below the lower detectability limit of both the liver ferritin and 2A4 assays Cultures were incubated at 37 °C in a humidified atmosphere of 5% CO_2 in air. Plates were scored for colonies after seven days of incubation, a time that has been shown previously to be optimal for the demonstration of inhibition of CFU-GM from normal donors by AIFIA.[14,15] All aggregates containing more than 40 cells were counted as colonies.

To study the neutralization of a possible isoferritin-associated inhibitory activity by a specific antibody, active isoferritin preparations were preincubated at 10^{-8} mol/L with the monoclonal antibody 2A4 prior to the culture. The final dilution of the ammonium sulfate precipitate of the 2A4 ascitic fluid was calculated so as to have an excess of antibody as compared to ferritin molecules

The bone marrow culture studies were carried out in a blind fashion. The various isoferritin preparations were made by two of us (S.L. and P.A.) and marked with different letters (A to H). People working with the CFU-GM assays did not know the content of such preparations Two plates were scored for each sample by two independent investigators, and the mean value of the four scores was considered the result of that single experiment. Colony growth in the presence of different preparations was expressed as a percentage of the control, and the results of different experiments were expressed

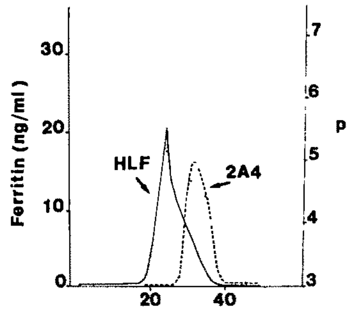

Fig 1. Isoferritin analysis of the heart ferritin preparation G containing only glycosylated isoferritins eluted from a Con A–Sepharose column with 0.1 mol/L α-methyl mannoside. In this analysis, isoferritins were separated on polyacrylamide gel isoelectrofocusing.[17] The bands containing isoferritins were cut and eluted. Then, on each sample, the pH was measured, and the ferritin concentration was evaluated by means of immunoradiometric assays based on polyclonal antibodies against human liver ferritin (HLF) and the monoclonal antibody 2A4 against human heart ferritin. Values for pH (· · · · · ·) and concentrations of liver-type (——) and heart-type (----) ferritin of different fractions are reported.

as means ±1 SD. Differences between means were determined by using the *t* test for paired observations after logarithmic transformation of the original colony scores (number per plate).

RESULTS

Isoferritin preparations. Table 1 summarizes the biochemical and immunologic characteristics of the ferritin preparations used in the following experiments. Liver ferritin preparations A and B did not show any significant differences in their isoelectrofocusing profiles or subunit composition as judged by SDS electrophoresis. Biochemical analyses of heart preparations C and D showed that these isoferritins had about 85% H subunits; their isoelectrofocusing profiles covered a large spectrum of isoferritins and were not distinguishable. The only difference between preparations C and D was that a minor portion (5%) of ferritin D bound specifically to Con A whereas ferritin C was 100% nonglycosylated. HeLa cell ferritin (preparation E) had approximately the same proportion of H subunits as heart ferritin and did not bind to Con A.

Preparations F and H could be characterized only immunologically because of the low level of ferritin purification, and the results of these studies are reported in Table 1. One major question addressed in this work was the relationship among subunit composition (immunologic reactivity), glycosylation, and pI. Figure 1 shows the results of isoelectrofocusing studies with the heart preparation G. A large number of isoferritin bands were seen, ranging in pI from 5.8 to 4.2. Immunoassays revealed two different isoferritin populations: (1) those detected by the 2A4 immunoradiometric assay and therefore containing more than 60% H subunits had a peak value of 4.6 for pI; (2) those detected by the immunoradiometric assay based on polyclonal antibodies against human liver ferritin and therefore rich in L subunits had a peak value of 5.2 for pI.

Effect of different isoferritins on CFU-GM growth. Results of these studies are reported in Table 2. Irrespective of the degree of glycosylation, the three preparations of human liver ferritin (A, B, H) did not show any effect on CFU-GM growth at concentrations equal to 10^{-9} and 10^{-12} mol/L. HeLa cell ferritin (preparation E) also did not affect colony formation. Of the two preparations of heart ferritin, preparation C, which had been passed through a Con A–Sepharose column to remove glycosylated proteins, did not show any effect on CFU-GM growth, whereas preparation D, containing 5% glycosylated ferritin, showed a significant inhibitory effect, mainly at 10^{-9} mol/L. Of the two heart preparations containing glycosylated isoferritins (F and G), G was found to produce a mean inhibition of 32% ± 11% of the control at

Table 2. Effects of Different Isoferritin Preparations on In Vitro CFU-GM Growth

Preparation (No of Experiments)	Molarity	Origin	Colony Formation as Percentage of Control Medium (Mean ± 1 SD)	Comparison With Control Medium*	
				t	*P*

Abbreviation. NS, not significant.

*Comparison was carried out by applying the *t* test for paired observations on colony scores after logarithmic transformation. Colony scores of the control medium ranged from 59 to 499 per plate.

10^{-9} mol/L, whereas F was ineffective. The major difference between these two preparations was that the step of heat extraction had been omitted with preparation F.

As reported in Table 3, a significant part of the inhibitory activity of preparations D and G on in vitro colony formation was removed by preincubation with the monoclonal antibody 2A4 directed against human heart ferritin.

Overall, nine experiments were carried out with heart ferritin preparations D and G at 10^{-9} mol/L. With ferritin D, colony formation was 70% ± 10% of the control medium, the difference being significant ($t = 5.14$, $P < .001$). With preparation G, colony formation was 68% ± 10% of the control medium, and the difference was again significant ($t = 7.40$, $P < .001$). In an attempt to investigate the reproducibility of our studies, we remade two preparations of heart ferritin according to the procedures followed with preparations D and G The new preparation D, D_1, produced at 10^{-9} mol/L an average inhibition of 24% ± 9%, which was significant ($n = 4$, $t = 4.80$, $P < .02$). Only two experiments were carried out with the new preparation G, G_1, at 10^{-9} mol/L, and colony formation was 79% and 68% of the control medium, respectively.

DISCUSSION

There is controversy surrounding the role of acidic isoferritins in the control of hematopoiesis.[11,17,24-26] According to Broxmeyer and his associates, the main characteristics of the acidic isoferritins that manifest suppressive activity upon the multipotential, granulocyte-macrophage, and erythroid progenitor cells in vitro are the following[26]: (1) they have a molecular weight of about 550,000 and a pI ranging from 4.6 to 4.9; (2) they bind to Con A and are specifically eluted by α-methyl mannoside; (3) they are inactivated by monoclonal antibodies prepared against human heart ferritin and H subunits from heart ferritin, but not by antibodies against liver ferritin; and (4) they are present in normal monocytes and macrophages and, in greater amounts, in leukemic cells.

Jacobs and his associates have noted a number of inconsistencies in the data of the Broxmeyer group and have raised the following criticisms[11,17,27]: (1) tissue ferritins, including those in monocytes and leukemic cells, are nonglycosylated or at least do not bind to Con A; (2) studies on human leukemic cell lines have shown no correlation between the ability of their extracts to inhibit human CFU-GM growth and their content in acidic, H-subunit–rich isoferritins; (3) biologic fluids, including serum, do not normally contain ferritins that react with antibodies against H-subunit–rich isoferritins; (4) AIFIA is reported to be active at concentrations as low as 10^{-18} mol/L, and this would mean approximately six molecules interacting with one cell within the target system; and (5) more important, the Jacobs group has not been able to demonstrate inhibition of granulocyte-macrophage progenitors by either heart, spleen, or serum ferritin[28]

Although inconsistencies do exist in the data of Broxmeyer and his associates,[15,16] not all the aforementioned criticisms are entirely valid.

1. Experimental evidence suggests that some 20% of ferritin subunits are made in the polyribosomes attached to the membranes of the endoplasmic reticulum.[1] This is the intracellular site at which export proteins secreted from cells are made and glycosylation takes place. It has also been suggested that some ferritin made by membrane-bound polyribosomes is assembled within vesicles and that this ferritin could be more acidic than the ferritin in the surrounding cytoplasm.[1] Shinjyo et al[29] reported fucose, mannose, galactose, and hexosamine in crystalline spleen ferritin. Previous studies in our laboratories[10] and some data of the present work show that in human liver, spleen, and heart a minor component of ferritin exists that binds to Con A and is specifically eluted with α-methyl mannoside. This fraction accounts for 2% to 5% of the total tissue ferritin and is generally richer in H subunits than is the total ferritin of the tissue extract.[10]

2. A variety of products from leukemic cells can affect in vitro granulopoiesis.[30] Consequently, there can be no simple relationship between immunologic characteristics of cell ferritin and the ability of cell extracts to inhibit colony formation.

Table 3. Effects of the Monoclonal Antibody 2A4 Against Human Heart Ferritin on the Inhibitory Activity of Acidic Isoferritins Against Human Granulocyte-Macrophage Progenitor Cells

Ferritin*	Monoclonal	No of Experiments	Colony Formation as Percentage of Control Medium (Mean ± 1 SD)	Comparison (t Test for Paired Observations)
D	none	5	68 ± 11	$t = 5\ 47$, $P < .01$ when compared with control medium
D	2A4	5	93 ± 12	$t = 4.37$, $P < .02$ when compared with D alone
none	2A4	5	100 ± 5	$t = 1.70$, $P > .05$ when compared with D + 2A4
G	none	5	67 ± 11	$t = 4.96$, $P < .01$ when compared with control medium
G	2A4	5	85 ± 13	$t = 6\ 91$, $P < .01$ when compared with G alone
none	2A4	5	100 ± 5	$t = 2.35$, $P <\ 05$ when compared with G + 2A4

With both preparations, colony formation after preincubation of the ferritin with the monoclonal 2A4 did not significantly differ from the control ($t = 2\ 30$ and $t = 1.29$, respectively, $P >\ 05$ in both cases). Colony scores of the control medium ranged from 57 to 474 per plate.

*In all experiments, the ferritin concentration was 10^{-9} mol/L.

3. Normal serum ferritin reacts with antibodies to liver or spleen ferritin, has a very low iron content, and is for the most part glycosylated.[2] Its concentration reflects the amount of storage iron, and it is believed that this protein is synthesized by the rough endoplasmic reticulum of reticuloendothelial cells and hepatocytes Acidic ferritins are present in many tissues, cells, and some biologic fluids, but cannot be detected in most sera or are present only in low concentrations.[31-33] A possible explanation for this has been recently advanced by Covell and her colleagues[34,35] and us.[33] It has been shown in fact that human serum contains binding factors for acidic ferritins, probably related to complement proteins. The interaction of H-subunit–rich ferritin with these binding factors may be responsible for the rapid clearance of tissue ferritin from circulation and the low levels of acidic isoferritins in the plasma of normal subjects. However, it should be noted that this does not rule out the possibility of a role of acidic isoferritins in local cell-to-cell interactions within the bone marrow. In fact, if acidic isoferritins had a local function, there would therefore be mechanisms to make sure that they do not accumulate in plasma and other body fluids.[35] Alternatively, as will be discussed, ferritin-binding proteins may play a role in the interaction of acidic isoferritins with cells.

4. The extremely low effective concentrations of AIFIA (10^{-16} to 10^{-18} mol/L) should not be considered biologic nonsense per se. It has indeed been found that the hematopoietic cell growth factors act at very low concentrations, and in addition, the receptor numbers per cell are extremely low.[36] There is also intriguing evidence that very few receptors need to be occupied to elicit a biologic effect, for example, as few as ten molecules of erythropoietin need to be bound to erythroid progenitors.[36] Within inhibitors of granulopoiesis, lactoferrin has been found to be effective in inhibiting colony stimulatory activity at concentrations as low as 10^{-17} mol/L by two different groups.[37,38]

In this work, we have tried to clarify the aforementioned controversy. Our findings clearly show that neither the pure form nor the glycosylated fraction of liver ferritin is able to consistently affect the in vitro growth of human CFU-GM. This is at variance with the findings of Broxmeyer et al,[15] who found that normal human liver and spleen ferritins had inhibitory activity at 10^{-10} to 10^{-15} mol/L. Our data, however, are in keeping with indirect clinical evidence. Patients with thalassemia major who are not regularly treated with desferoxamine may have serum ferritin concentrations as high as 20,000 μg/L (4×10^{-8} mol/L), about 50% of the circulating protein binding to Con A (M. Cazzola, unpublished observation). Their total white cell count and differential is either normal or may be slightly elevated, and leukopenia may be observed only as a part of the picture of severe hypersplenism.[39]

The results obtained with heart and HeLa cell ferritins are more intriguing. Only one of the two purified heart ferritin preparations and one of the two glycosylated fractions had a suppressive effect, whereas HeLa cell ferritin did not have any effect. The biochemical and immunologic analyses did not show major differences between active and inactive preparations. Only the differences in purification procedures and degree of glycosylation (Table 1) may explain, at least in part, the different effects on colony formation in vitro. The active purified heart ferritin preparation contained a minor portion (5%) of glycosylated ferritin, whereas the inactive one was fully nonglycosylated, as was the HeLa ferritin preparation. As regards the two glycosylated heart ferritin preparations (F and G), the active one (G) was heated and ultracentrifuged, whereas the inactive one (F) was not. The nonheated preparation, which is known to contain active proteases,[18] could have been partially damaged upon storage, even if phenylmethylsulfonyl fluoride had been added as a protease inhibitor. Inactivation of the suppressive activity of acidic isoferritin preparations D and G by preincubation with the monoclonal antibody 2A4 (Table 3) is one of the strongest indications that the inhibitory activity was associated with the acidic isoferritin molecules.

Although a high proportion of H subunits and glycosylation appeared to be prerequisites for the observed inhibitory effect, this activity appears to be much less potent than the previously reported AIFIA,[16] and its physiologic significance is uncertain. The inhibitory activity was detected by us at concentrations of 10^{-9} to 10^{-12} mol/L, and this means a range from 0.5 to 500 μg/L, assuming a molecular weight of 500,000. We have recently found that most normal subjects have serum concentrations of acidic ferritin lower than 1.5 μg/L (lower limit of detection)[33] and values are generally below 5 μg/L in patients with leukemia.[40] As previously pointed out, however, the low serum concentrations could be in keeping with the hypothesis of a local function.

The mechanism(s) by which acidic isoferritins exert their inhibitory activity are not clear at present. The active isoferritin preparations did not block in vitro growth of CFU-GM completely, the maximum inhibition being about 50%. This could mean that acidic isoferritins act on a subpopulation of human granulocyte-monocyte progenitors having specific receptors. For example, AIFIA has been found to suppress colony formation in vitro by an Ia-like (HLA-DR) antigen–positive subpopulation of cycling human CFU-GM.[41] Alternatively, the possibility exists that ferritin does not have a direct effect on myeloid progenitors but interacts with other active molecules There has been evidence that complement proteins may be ferritin binders in serum.[33,34] More recently, we have observed an in vitro interaction between H-subunit–rich isoferritins and the third component of human complement, C3 (V. Bellotti, P. Arosio, and M. Cazzola, unpublished observations). C3 is synthesized not only by the liver but also by macrophages and monocytes, as is the C3 proactivator, factor B.[42] Whether the interaction of acidic isoferritins and C3 can result in a reduced in vitro growth of myeloid progenitors remains to be established. Furthermore, it has been recently shown that lactoferrin can bind to ferritin, the ferritin-lactoferrin complex retaining its capacity of binding to lactoferrin receptors.[43] Since lactoferrin is able to inhibit colony stimulatory activity by binding to specific receptors on monocytes and macrophages,[37,38] the inhibitory activity of acidic isoferritins in the in vitro system could be explained by their capacity of interacting with lactoferrin.

It is hoped that a deeper insight into the effects of acidic isoferritins on in vitro growth of human myeloid progenitors will be obtained by using recombinant human homopolymers[44] and investigating the aforementioned mechanisms.

Abnormal In Vitro Differentiation of Peripheral Blood Clonogenic B Cells in Common Acute Lymphoblastic Leukemia During Complete Remission

By R. Consolini, J. Bréard, A. Bourinbaiar, A. Goutner, V. Georgoulias, C. Canon, E. Brugerie, and G. Mathé

An in vitro B cell colony assay system was used to evaluate B cell growth from peripheral blood precursors in common acute lymphoblastic leukemia (CALL) patients in remission during maintenance therapy and in normal controls. Major differences between the two groups were found in the phenotypic and morphologic features of pooled colony cells. In both cases, the cells were E−. Controls' cells were surface immunoglobulin (sIg)-positive, and some (mean, 25%) expressed Ia determinants. By Wright-Giemsa staining, they appeared as plasmacytoid cells. In contrast, patients' cells had predominantly a lymphoblastoid appearance, fewer cells had developed sIg, and a large fraction (mean, 43%) were Ia-positive. Moreover, the CALL antigen (CALLA) was expressed by a mean of 18% (range, 2% to 72%) of the patients' colony cells, whereas CALLA was never found in control colonies. Thus, cells with immature features persist in the colonies of CALL patients. Secondary colonies could be generated from the patients' cultured cells, indicating their self-renewal capacity. CALLA+ cells were also present in the secondary colonies. Finally, cytogenetic studies showed that a fraction of the patients' colony cells had karyotypic abnormalities similar to that of the original lymphoblasts. It is believed that in CALL patients this B cell assay permits the clonal expansion of residual circulating cells linked to malignant clones that are not detectable by classic hematologic and cytologic methods.

AN ACUTE LYMPHOBLASTIC leukemia (ALL)-associated antigen has been described by Greaves et al[1] on the surface of lymphoblasts from patients with the common variant of ALL (CALL). This antigen (CALLA) is also found in approximately one third of chronic myeloid leukemias in blast crisis as well as some T cell ALL (T-ALL) and non-Hodgkin's lymphomas (NHL).[2-4] However, despite its presence on leukemic blasts, CALLA is not leukemia specific, since it has also been detected on a small proportion of normal bone marrow (BM) cells, particularly in pediatric or regenerating marrows.[5,6] Extensive studies on the distribution of this determinant within normal tissues performed with specific rabbit heteroantisera and more recently with a murine monoclonal antibody (J5)[7] have shown a relatively broad cellular expression of CALLA, including a fraction of the cells in inflamed tonsils[8] as well as renal, gut, and breast epithelia,[9] and marrow stromal cells.[10] Within the hematopoietic lineage, however, CALLA is now considered to be a normal differentiation antigen associated with relatively immature lymphoid cells of T and mainly B lineage,[11] since it has been shown that most fetal CALLA+ cells are in early stages of B cell development and have a phenotype almost identical to that of CALL lymphoblasts.[12] The preferential expression of CALLA in early B cells, both normal and malignant, correlates with a number of recent reports that indicate that most CALL blasts belong to the B lineage.[13-17] Despite its lack of leukemic specificity, CALLA has been most useful for the differential diagnosis of leukemias along with other early differentiation markers. Its presence on a variable percentage of normal marrow cells, particularly during postchemotherapy-associated lymphocytosis,[6] prevents its use in the follow-up of CALL patients in remission. Numerous studies of the cellular distribution of CALLA have, however, shown that CALLA+ cells are never detected in the peripheral blood (PB) of healthy subjects.

We found that a small percentage of circulating CALLA+ cells were present in some CALL patients in remission receiving maintenance chemotherapy. A similar finding has been reported by Greaves et al[1] in an early study on the specificity of an anti-CALLA heteroantiserum. Such a phenotype seemed compatible with either the presence of residual leukemic cells or that of normal immature cells released inappropriately in the blood.[6] The very low representation of these cells within the PB, however, makes the determination of their nature technically difficult. We have therefore induced in vitro the clonal expansion of circulating B cells in these patients. We used a recently described technique that permits the generation of B cell colonies from both normal and malignant B lymphocyte progenitors.[18,19] The specificity of the technique resides in the exhaustive depletion of T lymphocytes from the starting population and in the use of irradiated T cells feeders together with T-conditioned medium.[18] This assay allows for the phenotypic and morphologic evaluation of the colony cells at the end of the culture. We have thus compared the differentiation of clonogenic B cells in CALL patients in complete remission (CR) to that of normal controls as well as T-ALL patients subjected to a similar maintenance chemotherapy regimen.

MATERIALS AND METHODS

Patients. A total of 20 CALL, five T-ALL, and two acute myeloid leukemia (AML) patients (aged 4 to 22 years) in CR entered the study; 16 of 18 CALL patients were in first remission, and four were in second remission. CR was checked in all cases by standard clinical and hematologic (less than 5% lymphoblasts in BM aspirates of normal cellularity) criteria. Patients were also monitored for the expression of CALLA+ cells in BM and PB CALL and T-ALL patients were on the same maintenance chemotherapy protocol (6-mercaptopurine daily, methotrexate weekly, and vindesine twice a month). A total of seven normal donors (aged 28 to 40 years) from the laboratory staff were also studied.

Cell separation Peripheral blood lymphoid cells (PBL) were separated on a Ficoll-Hypaque gradient (Pharmacia Fine Chemicals, Uppsala, Sweden) E− cells were obtained by rosette formation with two to five aminoethylisothio-uronium bromide hydrobromide

(AET) (Sigma Chemical Co, St Louis)–treated sheep red blood cells[20] at 4 °C for two hours followed by two successive Ficoll gradients E− cells were depleted of CALLA+ cells by complement-mediated lysis with the J5 monoclonal antibody kindly provided by Dr J. Ritz. Optimal lysis was obtained after a 30-minute incubation of 150 μL of J5 per 10^5 cells (dilution, 1/800, vol/vol in minimum essential medium [MEM, GIBCO, Grand Island, NY]) followed by a 45-minute incubation with 50 μL/10^5 cells of pretested guinea pig complement (dilution, 1/5 vol/vol, in MEM) (Institut Pasteur Production, Marne la Coquette, France) Complete removal of CALLA+ cells by this procedure was checked by indirect immunofluorescence in all cases. Treated cells were incubated with J5 antibody (1/800) and, after three washes, with fluorochrome (fluorescein isothiocyanate)-labeled goat F(ab')$_2$ antimouse Ig (Cappel Laboratories, Cochranville, Pa) The cells were then examined with a Zeiss microscope equipped with epillumination

In some experiments, E-J5− cells were further depleted of Ia+ cells, 10^5 cells were incubated with 150 μL of an anti-Ia monoclonal antibody (anti-I2) (Coulter Electronics, Hialeah, Fla) for 45 minutes at 4 °C with a subsequent incubation with guinea pig complement as described. In some cases, the presence of residual Ia+ cells, as detected by indirect immunofluorescence, led to a second complement-mediated lysis.

B cell colony assay The method described by Izaguirre et al[18] has been used In brief, 2 × 10^5 cells from both cell fractions (E− and E-J5−) were seeded in 0.8% methyl cellulose in MEM supplemented with 10% fetal calf serum (FCS) (GIBCO), 20% conditioned medium, and 3 × 10^5 normal irradiated T lymphocytes obtained from two normal donors. Conditioned medium was prepared by incubating normal T cells with 1% phytohemagglutinin (PHA, HA-16) (Wellcome) in growth medium (MEM, 10% FCS) at 37 °C in a 5% CO$_2$ atmosphere for two days. Supernatants were collected, filtered, and stored at 4 °C. Such preparations are termed PHA–T cell–conditioned medium (PHA-TCM). Normal irriadiated E+ cells were prepared from normal PBL by rosette formation with AET-SRBC, and centrifugation was done over a Ficoll-Hypaque gradient E+ cells were recovered from pellet by hypotonic lysis of the SRBC, washed twice, and irradiated with 2,500 rad from a Co source. The same T lymphocyte donors and PHA-TCM batch were used in this study Measured 0.1-mL aliquots of this preparation were distributed into the wells of a microtest plate with a flat bottom (Falcon Labware, Oxnard, Calif). The plates were incubated at 37 °C for five to seven days in a moist atmosphere with hypoxemic conditions (7% O$_2$).

Colony characterization Aggregates of more than 20 cells were counted as colonies under an inverted microscope. Individual colonies were then picked with a fine-capillary pipette containing cold phosphate-buffered saline and pooled and washed for further characterization. The cells were tested for expression of the E receptor (by SRBC rosette formation) and for the presence of surface immunoglobulins (sIg) with a fluorescein-labeled goat F(ab')$_2$ anti-human F(ab')$_2$ fragment (polyvalent) (Cappel Laboratories) The cells were also phenotyped with various monoclonal antibodies for the presence of Ia (Anti-I1) (Coulter Electronics), CALLA (J5) (donated by Dr Ritz), and a B cell–specific antigen B1 (anti-B1, donated by Dr Nadler) I1, J5, and B1 were tested by indirect immunofluorescence using fluorescein-labeled goat antimouse immunoglobulin (Cappel Laboratories) Furthermore, slides were prepared by centrifugation and stained with Wright-Giemsa for morphologic study.

Self-renewal experiments Colonies were picked, pooled, and washed, and 5 × 10^4 to 10^5 cells were replated as in the primary cultures After five to seven days, colonies were counted and characterized.

Cytogenetic analysis. Chromosome analysis was performed in the colony cells of four patients To obtain metaphases, individual colonies were picked and pooled in 0.2 mL PBS. Colcemid was added at a final dilution of 0 01 μg/mL, and cells were incubated at 37 °C for 60 to 90 minutes. Cells were exposed subsequently to a hypotonic solution with 0.075 mol/L KCl and fixed in methanol acid acetic (3:1, vol/vol) Air-dried slide preparations were made, stained with Giemsa, and examined microscopically for well-spread metaphases The chromosomal structure was studied using the G-Tzypsin Giemsa (GTG)[21] banding technique. Slide preparations were submerged in a trypsin solution (0.1%) (Sigma Chemical Co) at 22 °C for 40 to 120 seconds and stained with Giemsa The international nomenclature was used [22]

RESULTS

CALLA+ cells in BM and PB. The percentages of CALLA+ cells in BM and PB of 20 CALL patients in remission are presented in Table 1. As can be seen, more than 5% J5+ cells were detected in the BM of four of these patients. BM cellularity was normal in these cases, with no evidence of lymphocytosis. Of note is patient 11 who presented with a regenerating BM with 25% lymphocytes but had no detectable J5+ cells. The proportion of CALLA+ cells in the PB of these patients was 0% to 3% and reached 15% in one case. Removal of T lymphocytes prior to testing resulted in a minor change (1% to 2% increase) in the remaining E− population; 200 cells were examined (Table 1). PBL from five T-ALL and two AML patients as well as seven healthy volunteers were negative for J5 except for one T-ALL patient who had 2% circulating CALLA+ cells. It has recently been reported that polymorphonuclear cells react with J5.[23] However, no correlation could be made

Table 1. CALLA+ Cells in BM and PB of CALL Patients in Remission

between the weak staining that we found on these cells and the bright fluorescence of J5+ lymphoid cells.

Colony formation. Normal PB E− cells could generate between 100 and 900 colonies/10^5 plated cells. Cells from the colonies were pooled and characterized for various surface markers. They had no receptor for SRBC, and 65% were sIg+ and 25%, Ia+. In addition, in two subjects tested, 40% and 58% of the colony cells expressed the antigen B1.[14] This phenotype (E−, sIg+, B1+) is characteristic of mature B cells and demonstrates that these culture conditions allow the specific growth of B lineage cells. Morphologic studies confirmed these observations since most of the colony cells had a plasmacytoid appearance as judged after Wright-Giemsa staining. Of note is the fact that none of the cells present in these colonies bore the CALLA antigen, as shown by their lack of reactivity with the J5 antibody.

E− cells from CALL patients in remission were cultured under the same conditions, and the assay was technically satisfactory in 15 patients (cases, 1 to 15). From 20 to 2,400 colonies/10^5 cells were generated As was the case for normal subjects, very few E+ cells were present in the colonies. A total of 57% of these cells were sIg+, which is less than in controls, and 43% were Ia+, significantly more than in normals ($P < .01$). Moreover, in two cases out of two, more than 50% of these cells were stained by the B1 monoclonal antibody (68% and 50%) These results are thus suggestive of a B cell nature for most of these patients' colony cells. A major phenotypic difference, however, was found between the cells derived from CALL patients and those of normal subjects since a mean of 18% of the former expressed CALLA (range, 2% to 72%; Fig 1). The morphology of the patients' colony cells also showed that they were not similar to the controls' cells, since most of them had a lymphoblastoid appearance. Both surface markers and cytologic criteria therefore seemed to indicate that colony cells derived from B precursors are less differentiated in CALL patients in remission than in normal subjects.

To assess whether chemotherapy could affect the differentiation of B cells, five T-ALL and two AML patients in remission and under the same maintenance treatment were tested. From 150 to 500 colonies/10^5 plated cells were generated in T-ALL. A total of 65% of these cells were sIg+ and 28% Ia+, the phenotype being similar to that observed in normal colonies. In all cases, no J5+ cells were detected in the colonies, even in T-ALL patient with circulating J5+ cells (Fig 1).

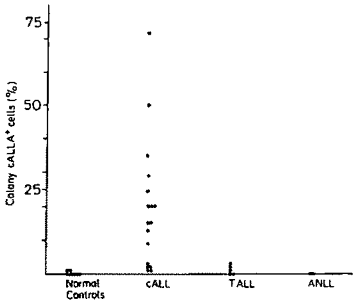

Fig 1. J5-positive cells in pooled colonies generated from the E− cell fraction.

Characterization of B colony-forming cells (B-CFC). An interesting observation was the lack of statistically significant correlation between the proportion of J5+ cells in the colonies of CALL patients and the level of circulating J5+ cells. Therefore, in these patients we studied the differentiation of B-CFC under the same culture conditions but after elimination by complement-mediated lysis of the J5+ cells present in the E− populations. The colonies could be analyzed in 11 patients (cases 1 to 11); lysis of J5+ cells prior to culture did not significantly alter either the plating efficiency (268 ± 145 *v* 354 ± 260 colonies/10^5 cells in the controls, 858 ± 891 *v* 628 ± 526 colonies/10^5 cells in the CALL patients) or the phenotype (E−, sIg+, Ia+) in both controls and CALL patients. A major phenotypic difference, however, was found between the cells derived from CALL patients and those of normal subjects, since a mean of 17% of the former expressed CALLA (range, 2% to 65%). These observations seemed to indicate that in CALL patients, CALLA+ cells can be generated in vitro from CALLA− progenitors.

To further characterize the phenotype of B-CFC, E− cells were treated with anti-Ia antibody (1:600 vol/vol) in addition to J5 (1:800 vol/vol) in two CALL patients and three controls. In both groups this pretreatment led to an abrogation of colony growth (27 ± 6 *v* 104 ± 31 colonies/10^5 cells in the controls, 50 ± 12 *v* 415 ± 49 colonies/10^5 cells in CALL patients), suggesting that the B progenitor cells in normal subjects as well as in the patients bear the Ia antigen. The presence of Ia antigen on normal B-CFC has already been reported by Taetle et al.[24] To assess that the effect of the anti-Ia antibody was not due to a depletion of an accessory cell population, which could be critical to colony growth, increasing numbers of autologous (10^4 to 10^7 cells/mL) adherent cells were added to the E−, J5−, Ia− cell population. The presence of these monocytes could not restore colony growth (unpublished data).

Self-renewal. To investigate the clonogenic capacity of B colony cells from CALL patients and controls, primary colonies were picked individually, pooled, and replated as primary colonies. A significant secondary plating efficiency (PE2) was observed in four of four patients studied. Although considerable variation was present among the patients, essentially no differences were evident between E− and E-J5− secondary plating efficiencies. The proportion of J5+ cells in the secondary colonies was comparable to that found in the primary cultures These results seem to indicate that some colony cells present self-renewal capacity similar to that of stem cells. In contrast, PE2 in controls was very low (inferior to five colonies/10^5 seeded cells) either in E− or in E-J5− fractions.

Cytogenetic analysis. The karyotype of cultured cells was studied in four patients for whom chromosomal abnormalities had been found in the original lymphoblasts (Table 2) During the acute phase, three patients had a mosaic composition of BM lymphoblasts, with 33% of the cells carrying a marker for the first patient, 55% for the second, and 25% for the third patient, the marker being different in each case. Cytogenetic examination of 22 mitoses in the colony cells of the first patient revealed that one cell (ie, 5%)

							5% 46XY +21 −19

had the same marker as the lymphoblasts. In the second patient, out of 20 mitoses studied, one cell had the same marker (mar 1) as the original malignant clone, one cell displayed a new marker (mar 2) and one cell had both markers (mar 1 + mar 2). Thus a total of 15% of the cells had chromosomal aberrations. In the third patient, cytogenetic examination of colony cells revealed a reduction of the hyperploidy observed on 25% of the initial lymphoblasts (from 53 to 47 chromosomes) in 20 mitoses studied; two of them had the same marker as the original malignant clone. The fourth patient had Down's syndrome, presenting a change of the modal chromosome number on 33% of the lymphoblasts at diagnosis (Table 2); out of 20 mitoses studied in the colony cells, one cell shared the loss of the same chromosome (−18), and three cells displayed the loss of three other different chromosomes (Table 2). It is interesting to note that the percentage of J5+ cells in the colonies of these patients was 4%, 20%, 24%, and 33% respectively. In a fifth patient, no chromosome abnormalities were present in the colony cells or in the blasts at presentation (unpublished data).

DISCUSSION

To induce the clonal expansion of circulating B cells in CALL patients in remission, we used an in vitro assay that was found suitable for the generation of B cell colonies from malignant progenitors in CALL,[19] chronic lymphocytic leukemia,[25] B cell non-Hodgkin's lymphoma,[18] and from normal precursors in healthy subjects.[18] B cell colonies derived from normal controls are composed of E−, sIg+, Ia+, B1+ cells that have a plasmacytoid appearance. Patient's colony cells are composed of E−, B1+ (in two cases tested); sIg is expressed on fewer cells than in normals. The Ia determinant, which is lost during the final stages of B cell maturation, is retained by a significantly greater proportion of the patients' colony cells Moreover, a variable fraction of these cells express CALLA, which is associated with immature B cells. In addition, they predominantly have a lymphoblastoid appearance contrasting with the uniform plasmacytoid features of normal colony cells. Taken together, these results suggest that some circulating B cells from CALL patients in remission cannot differentiate in vitro under culture conditions that permit the maturation of normal B cells.

Since it has been shown that chemotherapeutic treatment can induce abnormalities of in vivo lymphopoiesis in leukemic patients,[6,26,27] we have studied T-ALL and AML patients during maintenance therapy. In contrast to CALL, no circulating J5+ cells were detectable in any of these patients except one. In addition, the phenotype and appearance of their B colony cells were identical to those of normal controls. Thus, it seemed unlikely that the chemotherapeutic regimen induced the abnormal in vitro growth pattern of B cells in CALL patients.

A high number of secondary colonies was observed in all four patients for whom primary colony cells were replated, whereas very few secondary colonies could be generated in the controls. Thus, some of the patients' colony cells were capable of self-renewal, a property usually associated with stem cells and malignant cells.

The results of cytogenetics studies in four patients clearly showed that some colony cells were derived from the original malignant clone. In all cases, a fraction of the cultured cells presented a chromosomal aberration identical to that previously found in the initial lymphoblasts. It thus appeared that despite complete hematologic remission these patients had in their PB residual cells belonging to the malignant clone. The expansion of these circulating precursors during the culture allowed the detection of their abnormal progeny by classic cytogenetic methods. All patients are still in remission, two of them more than 18 months after being studied. Since chromosome examination and study of surface markers cannot be done on the same cells, we could not determine the phenotype of the colony cells with chromosomal aberrations. It should be noted that in all cases the percentage of J5+ cells and number of abnormal metaphases in the colonies were comparable. However, further work is needed to establish whether the clonal cells express the J5 determinant. Double staining for J5 and surface or cytoplasmic light chains could be helpful but is subjected to the concomitant expression of CALLA and Ig light chains by the same cell. Such a phenotype has not been described in normal cells and can be induced in vitro in CALL leukemic blasts of only some patients.[16,17] In any case, fluoresceinated anti-κ and anti-λ chains will be used instead of polyvalent anti-F(ab')$_2$ in our subsequent studies to evaluate the distribution of these markers in the whole colony population and eventually in the J5+ fraction.

Since the elimination of CALLA+ cells from the starting population did not alter the phenotype of the cultured cells, it appears that the J5+ colony cells are not, or at least not exclusively, derived from the circulating J5+ cells detected in these patients. The J5+ antibody has been shown to induce the modulation of the CALLA molecule.[28] However, under the technical conditions used in this study (ie, incubation with J5 at 4 °C and subsequent incubation at 37 °C after the addition of complement), lysis is likely to occur prior to any modulation. These results can be compared to the data of Izaguirre and Greaves[29] who showed, by separating CALL blast cells into J5+ and J5− fractions, that CALLA does not seem to be a marker for all potentially clonogenic CALL blasts.

Finally, it is worth mentioning that during the course of this study, three patients (cases 1, 2, 13) relapsed 1, 5, and 2 months, respectively, after being studied. The proportion of J5+ cells in the colonies was 50%, 72%, and 13% respectively. Two of these patients (1, 13) had virtually no BM or PB CALLA+ cells at the time of study. Moreover, no patient in the group of less than 5% CALLA+ colony cells has relapsed thus far. More extensive follow-up might indicate whether a correlation between the percentage of CALLA+ colony cells and subsequent clinical course can be established.

In conclusion, we have shown that some circulating B clonogenic cells of CALL patients in remission do not differentiate in vitro under experimental conditions that allow the maturation of normal B cells. The self-renewal capacity of some of those cells, the presence of an identical karyotypic abnormality in some cultured cells in the original lymphoblasts, and the subsequent relapse of three patients who had a relatively high proportion of J5+ colony cells seem to indicate that this culture system permits the clonal expansion of residual circulating cells linked to the malignant clone. This observation might be of biologic as well as clinical importance, since these residual cells cannot be detected by classic hematologic, cytologic, and even immunologic methods. It would be of interest to study with the same colony assay the differentiation of B cells in CALL patients who are in long-term remission and not receiving therapy

Application of Hyperthermia to the Treatment of Human Acute Leukemia: Purging Human Leukemic Progenitor Cells by Heat

By Yoshiaki Moriyama, Miwako Narita, Ken Sato, Masaru Urushiyama, Satoru Koyama, Hideo Hirosawa, Kenji Kishi, Masuhiro Takahashi, Kazue Takai, and Akira Shibata

The application of hyperthermia to the treatment of neoplastic disease has focused on solid tumors. Since the hyperthermic sensitivity of human acute leukemia cells is not known, we have studied the in vitro response of human leukemic progenitor cells (L-CFU) to hyperthermia using a quantitative assay system for L-CFU. Human L-CFU were found to be more sensitive than committed normal myeloid progenitor cells to hyperthermic killing (41 to 42 °C). In addition, in the five acute myelogenous leukemic patients studied, it was shown that their leukemic progenitor cells—all types were studied according to the French-American-British diagnosis—were unable to form colonies when exposed to a temperature of 42 °C for 60 minutes, whereas the residual normal clones suppressed by the leukemic cell population were found to recover and to form more colonies in vitro as compared with untreated leukemic marrows. This strongly suggests that in vitro hyperthermia may selectively purge residual leukemic cells, especially L-CFU in stored remission bone marrow before autologous bone marrow transplantation.

© *1986 by Grune & Stratton, Inc.*

IN THE PAST DECADE, there has been considerable interest in the use of hyperthermia to treat cancer. Elevated temperatures of 41 to 46 °C have been amply demonstrated to inhibit proliferation of malignant cells, which are more sensitive to hyperthermic killing than their normal cell counterparts.[1-3] However, there has been no information on the thermal sensitivity of progenitor cells (L-CFU) from human acute myelogenous leukemic patients (AML), which give rise to colonies consisting of leukemic cells.[4,5] We investigated the effect of hyperthermia on human L-CFU in vitro, using a quantitative human L-CFU assay developed specifically to clone myeloid leukemia by preincubation of leukemic cells with phytohemagglutinin–lymphocyte-conditioned medium (PHA-LCM).[6,7] The results showed that L-CFU in human acute leukemia are more sensitive than committed normal myeloid progenitor cells (CFU-c) to temperatures of 41 and 42 °C. These results suggest that in vitro hyperthermia may selectively eradicate residual leukemic cells in stored bone marrows prior to autologous bone marrow transplantation in humans.

MATERIALS AND METHODS

Leukemic cells Human leukemia cells (57% to 95%) for L-CFU assay were obtained from five patients with AML prior to chemotherapy (Table 1) Normal marrow cells used as controls were obtained from two normal volunteers and from three patients with acute leukemia in complete remission. The marrow cells were aspirated from the sternum or posterior iliac crests using conventional techniques and diluted immediately in McCoy's 5A medium (GIBCO, Grand Island, NY) containing heparin (10 U/mL) The buffy coat was obtained by centrifugation for five minutes at 200 g and washed twice with McCoy's 5A medium. In one patient studied, peripheral blood was obtained by venipuncture into heparinized syringes. Mononuclear cells were then separated by layering the blood over Lymphoprep (Nyegaared, Oslo) and centrifuging for 25 minutes at 400 g Cells in the interface band were harvested and washed twice with McCoy's 5A medium For heating, the cells obtained were adjusted to 2 × 10^6/mL.

Heating Cells suspended in 1 mL of McCoy's 5A medium in Falcon 3033 culture tubes (Falcon Labware, Oxnard, Calif) were immersed in a constant water bath (±0.1 °C) and exposed to temperatures of 41 and 42 °C for 15 to 60 minutes Control cells were kept at room temperature for the same time period After hyperthermic treatment, the cell suspension was immediately cooled in water (4 °C) and prepared for L-CFU and CFU-c assay.

Stem cell assays. Basically, our PHA assay for L-CFU consists of two phases: an initial liquid phase of 15 to 24 hours at 37 °C and a semisolid phase for seven days of incubation[6] Briefly, in the liquid phase, 0.1 mL (for one plate) of McCoy's 5A medium containing 2 × 10^5 marrow or peripheral mononuclear cells was cultured without any serum in a Falcon 3033 culture tube to which 0.05 mL PHA-LCM was added. After preincubation, the cells were not washed, but diluted with 0.9 mL of 0.3% agar medium (enriched McCoy's 5A medium[8] + 15% fetal calf serum) and pipetted carefully to create a single-cell suspension. After being resuspended in an agar medium, the cells were plated into 35-mm Falcon Petri dishes and cultured in a solid phase without any other stimulators.

The CFU-c assay was performed according to the method of Burgess et al[9] using human placenta-conditioned medium (HPCM) as a source of colony-stimulating factor (CSF) to compare to the thermal sensitivity of L-CFU. All cultures were done in duplicate or triplicate

After seven to ten days of incubation in a 5% CO_2 gas-controlled humidified incubator at 37 °C, colonies containing 40 or more cells were counted with an inverted microscope. For determining stem cell survival, the ratio of the colony count in each heated sample to the mean control colony count was calculated.

RESULTS

A comparison between the thermal sensitivity of human L-CFU and CFU-c is illustrated in Fig 1. The survival of leukemic progenitor cells in AML (patient T.O) decreased exponentially with continuous heating at temperatures of 41 and 42 °C. At both temperatures the survival curves for L-CFU had an initial shoulder region. At 42 °C the survival of CFU-c also decreased exponentially, but was not affected at the lower temperature of 41 °C. The terminal slopes of the curves clearly demonstrated greater hyperthermic sensitivity of L-CFU when compared to CFU-c at both temperatures studied. The slope of the exponential portion of the curves for L-CFU increased over ten times with a 1 °C rise in tempera-

ture, whereas that for CFU-c increased only about 1.8 times.

FAB diagnosis,[10] the clinical outline of five patients with AML, and the thermal sensitivity of L-CFU in each patient at 42 °C are summarized in Table 1. All leukemic progenitor cells (L-CFU) studied, even those producing any type of leukemic cells according to FAB diagnosis, were found to be very sensitive to heat at 42 °C. In addition, L-CFU obtained from four out of five patients were completely killed by heat for 60 minutes at 42 °C and therefore unable to form colonies in vitro, whereas 54% of normal CFU-c survived for the same time period.

To see whether hyperthermic treatment could save normal clone but selectively eradicate leukemic cell populations in leukemic marrows containing normal clone, the possibility that residual normal clones suppressed by the leukemic environment could be detected after purging the leukemic cell population by hyperthermia was examined using a standard agar method.[9] Table 2 is based on the data of an experiment in which four leukemic marrows containing 57.5% to 98.8% blasts were cultured for a CFU-c assay using HPCM as a source of CSF before and after heating for 60 minutes at 42 °C, and three out of these four leukemic marrows were also investigated by an L-CFU assay. The four untreated leukemic marrows obtained from three patients with AML and one with acute lymphocytic leukemia (ALL) grew none or a few CFU-c–derived colonies in an agar medium. After hyperthermic treatment, on the other hand, the L-CFU population disappeared (in three out of four patients, see Table 1), but the residual normal CFU-c in all of the four leukemic marrows studied remained active and appeared to form more colonies in vitro.

DISCUSSION

Human acute leukemia is considered to be a clonal hemopathy originating in pluripotential stem cells, and leukemic cells are produced by L-CFU, which are able to self-renew and proliferate in vitro.[7,11,12] Therefore, it is necessary to eradicate the L-CFU population in the bone marrow of patients for a successful treatment of acute leukemia. In humans, attempts have been made to purge malignant cells from marrow using 4HC, ASTA-Z-7557, and monoclonal antibodies.[13-15] Experience is still too limited to evaluate the success of these agents.

In this study, using a quantitative assay system for L-CFU, we clearly demonstrated that the survival of human L-CFU decreases exponentially with continuous heating at temperatures of 41 and 42 °C and that L-CFU in AML are more sensitive than CFU-c to hyperthermic killing. In addition, most of the L-CFU obtained from the marrow or peripheral mononuclear cells of five patients with AML appeared to be unable to form colonies and were eradicated by heat at 42 °C for 60 minutes, whereas over half of the normal CFU-c remained active and survived for the same time period.

‡Patient with ALL (blasts in bone marrow, 98 8%)

In general, leukemic marrows in humans contain normal clones, but these normal clones are usually suppressed by a leukemic cell population, showing almost no growth of CFU-c–derived colonies in vitro.[16] However, after heating leukemic marrow cells in vitro, residual normal clones (CFU-c) appeared and formed more colonies than untreated marrows, indicating the possibility of purging a leukemic cell population selectively by heat. The loss of the clonogenic capacity of L-CFU with heat is not understood but may be caused by an alteration of cell morphology or perturbation of the cytoskeletal system.[3,17,18] In studies with the AKR murine model, Robins et al[3] demonstrated by electron micrographic studies of AKR leukemia cells treated with 41.8 °C that structural damage to the cell, ie, changes in the Golgi apparatus, was associated with the lack of ability to form colonies and that this decrease in colony formation resulted in increased survival in leukemic AKR mice that received 41.8 °C whole-body hyperthermia. In addition, the electron microscopic studies on the CA755 murine model demonstrated that the Golgi apparatus changes induced by heat correlated with tumor cell death, with an increase in survival, and with cures in some animals.[18] These observations suggest that the lack of the ability of heated leukemic cells to form colonies may represent cell death. Interestingly, however, murine stem cell studies[19,20] also suggested that pluripotential stem cells (CFU-s) are less sensitive than CFU-c to hyperthermic killing because of a division delay of CFU-s, which mostly remain in the G_0 phase.[21] This finding seems to be important for keeping the CFU-s population, which is essential to hematopoietic regeneration after bone marrow transplantation, from being killed while purging residual leukemic cells in stored bone marrows by heat.

From these and our previous results, we emphasize that the in vitro treatment of stored remission bone marrow with hyperthermia may selectively eradicate the L-CFU population before autologous bone marrow transplantation. Thus, in vitro hyperthermia may be a useful tool in clinical bone marrow transplantation for the treatment of human acute leukemia as an alternative to monoclonal antibody treatment for purging leukemic cells in vitro.

Role of Arginine Residues in the Coagulant Activity of High Molecular Weight Kininogen

By Jin-Jyi Chang, Cheryl F. Scott, and Robert W. Colman

High molecular weight (HMW) kininogen, the cofactor for activation of the contact system of plasma proteolysis, transports and optimally positions prekallikrein and factor XI on a negatively charged surface, allowing those zymogens to be activated by surface-bound factor XIIa. HMW kininogen circulates in plasma as a procofactor that, after cleavage by kallikrein or factor XIIa, gains ability to bind to the surface. The mechanism responsible for this increased affinity for the surface is unknown. We hypothesized that modification of arginine residues may prevent cleavage of HMW kininogen, since the initial kallikrein-induced cleavage sites on the HMW kininogen molecule are at the NH_2 terminal and the COOH terminal of the bradykinin-containing portion of the molecule, each of which contains arginine. We found that modification with butanedione of four arginine residues in the HMW kininogen molecule prevented bradykinin release, which results from cleavage of HMW kininogen. Furthermore, HMW kininogen coagulant activity was lost, in proportion to the degree of arginine modification, until 6.6 residues had been modified. Complex formation with prekallikrein, however, was found to be unaffected by the modification of modified HMW kininogen. To account for the loss of coagulant activity, we also examined the ability of modified HMWKa (active cofactor) to bind to an activating surface. The affinity of modified HMWKa for kaolin was tenfold less than the affinity of unmodified HMWKa. These data suggest that arginine residues play a critical role in the ability of HMW kininogen to function as an activation cofactor, both by preventing the cleavages that produce HMWKa as well as by decreasing the affinity of HMWKa for the surface.

© 1986 by Grune & Stratton, Inc.

HIGH MOLECULAR WEIGHT (HMW) kininogen functions as the cofactor of surface-mediated defense reactions[1] by virtue of its ability to position optimally the zymogens, prekallikrein[2] and factor XI,[3] that exist in plasma as biomolecular complexes with HMW kininogen, on the surface where these zymogens can be cleaved by activated factor XII[4–7] Plasma kallikrein cleaves HMW kininogen to disulfide-bridged heavy and light chains, releasing bradykinin in the process. The light chain of HMW kininogen expresses the coagulant activity, since it contains both the surface-binding region as well as the domain for complex formation with either prekallikrein or factor XI.[8]

Recently, we found that HMW kininogen exists as a procofactor, since after proteolysis by kallikrein, the ability of the cleaved protein (HMWKa) to adsorb to a kaolin surface in the presence of plasma concentrations of fibrinogen[9] is markedly enhanced. The molecular changes responsible for this increased affinity for the surface are unknown, since the amino acid residues responsible for the ability of human HMW kininogen to adsorb to surfaces have not been elucidated. In bovine HMW kininogen, it has been suggested that the positively charged residues in a histidine-rich area of the molecule[10] may be critical for binding. We hypothesized that since the primary cleavage sites in the HMW kininogen molecule by plasma kallikrein are on either side of the bradykinin moiety[11] and that since bradykinin contains arginine at both its NH_2 terminal and COOH terminal, modification of arginine residues might prevent cleavage of HMW kininogen by plasma kallikrein. After covalently modifying from 2 to 17 of the 35 arginine residues in HMW kininogen with butanedione, we assessed the effect of these molecular alterations on HMW kininogen by examining coagulant activity, proteolytic cleavage, release of bradykinin, binding to a negatively charged surface, antigenicity, and ability to form a complex with prekallikein.

MATERIALS AND METHODS

Reagents All chemicals used were reagent grade or better Butanedione was purchased from Aldrich Chemicals, Milwaukee. Sodium dodecyl sulfate (SDS), ammonium persulfate, methylene bis-acrylamide, acrylamide, and high and low molecular weight standards (200,000; 116,000; 93,000; 66,500; 45,000; 31,000; 21,000; 14,000) were purchased from Bio-Rad, Richmond, Calif. Dithiothreitol and iodoacetate were obtained from Pierce Chemical Co., Rockford, Ill. Soybean trypsin inhibitor and β-mercaptoethanol were purchased from Sigma Chemical, St Louis. Glass tubes (6 × 50 mm) and kaolin (acid washed) were obtained from Fisher Scientific Co, King of Prussia, Pa. Inosithin was purchased from American Concentrates, New York. Coomassie brilliant blue R-250 was purchased from LKB, Rockville, Md D-Pro-Phe-Arg-*p*-nitroanilide (S-2302) was obtained from Helena Laboratories, Beaumont, Tex Corn trypsin inhibitor was a gift from Dr Edward P. Kirby of the Temple University Health Sciences Center.

Plasma. Normal pooled plasma, used as a reference standard, was purchased from George King, Biomedicals Inc, Overland Park, Kan Prekallikrein-deficient plasma was graciously supplied by Dr Charles Abildgaard, Davis, Calif. Plasma deficient in total kininogen[12] was donated directly to us by Mrs M. Williams, Philadelphia.

Amino acid analysis. Composition of HMW kininogen and the separated polypeptide chains was determined after hydrolysis with 6N HCL at 110 °C for 20, 40, and 60 hours, using the Glenco MM070 micro amino acid analyzer with the Pico System II buffer system (Pierce Chemical Co, Rockford, Ill). The values for serine and threonine were extrapolated to zero time.

Purified plasma proteins. Purified plasma kallikrein was prepared, as previously reported by our laboratory, by activation of purified prekallikrein[13] with factor XII fragments (XIIf) The activation was stopped by inhibiting the XIIf with purified corn trypsin inhibitor (50 μg/mL) The preparation of kallikrein contained no measurable factor XI, XIa, XII, XIIa, plasminogen, or plasmin, as determined by coagulant and amidolytic assays. The preparation, unreduced, showed a doublet (88- and 85-kDa); reduced, it showed a heavy chain of 52-kDa and two light chains of

36- and 33-kDa. The assay of kallikrein was performed with the amidolytic substrate, S-2302.[13] The specific activity was 55 μmol S-2302 hydrolyzed/min/mg protein.

HMW kininogen was prepared by the method of Kerbiriou and Griffin.[14] On reduced SDS polyacrylamide gel electrophoresis (PAGE), 90% of the molecule was in the form of the intact 120-kDa polypeptide. The specific coagulant activity varied from 15 to 23 U/mg The coagulant activity of the intact molecule or its chains was determined by a modification of the partial thromboplastin time, as previously detailed.[9] The protein concentration of HMW kininogen was determined by measuring UV absorption using $A^{1\%}_{280\ nm}$ = 7 0[14] as well as from amino acid analysis.

Modification of HMW kininogen and cleaved HMW kininogen with butanedione. Modification of arginine residues of HMW kininogen or cleaved HMW kininogen (HMWKa) with butanedione was performed according to the method of Riordan.[15] HMW kininogen (33 μmol/L) was diluted in 50 mmol/L sodium phosphate buffer, pH 7.4, and various amounts of butanedione, diluted 1:100 in the same buffer, were added At various time intervals, aliquots of reaction mixture were pipetted into equal volumes of glacial acetic acid to stop the reaction. HMW kininogen coagulant activity was determined at each time point by pipetting a suitable amount (1 to 2 μL) of the reaction mixture into tubes containing coagulation reagents HMW kininogen with or without acetic acid at time zero had identical coagulant activity. The number of arginine residues modified was determined by difference from amino acid analysis as described above after freeze-drying the acidified aliquots, since the modified arginines are not detected on the chromatograms

Preparation of cleaved HMW kininogen (HMWKa). HMW kininogen, intact or modified with butanedione, was incubated with kallikrein using the conditions described by Scott et al.[9] In brief, HMW kininogen in .015 mol/L Tris-acetate, pH 8.0, was incubated with kallikrein (molar ratio of 1.100) at 37 °C. At specific times, aliquots were pipetted into microfuge tubes containing a tenfold molar excess of soybean trypsin inhibitor to inhibit kallikrein and stop the cleavage process. A portion of the aliquot was reduced with dithiothreitol (DTT) (1 mmol/L) and subjected to SDS-PAGE according to the method of Laemmli,[16] and the remainder was used for determining the release of bradykinin. Since the cleavage of the two bonds liberating bradykinin are virtually simultaneous, HMWKa is defined for this study as kinin-free HMW kininogen.

Measurement of bradykinin release. Bradykinin was measured using a radioimmunoassay according to the procedure of Proud et al[17] as previously reported.[9] The antibody against bradykinin was a generous gift of Dr David Proud (Baltimore, Md).

Radiolabeling of HMW kininogen. ^{125}I-HMW kininogen was prepared by radiolabeling purified HMW kininogen by the Iodogen method[18] as previously reported.[9] The specific radioactivity was 1 5 × 10^6 cpm/μg. This process did not alter the coagulant activity of the HMW kininogen. The ^{125}I-HMW kininogen was cleaved to ^{125}I-HMWKa as described above. In some cases, the ^{125}I-HMW kininogen was modified with butanedione prior to incubation with kallikrein.

Binding of ^{125}I-HMWKa and butanedione-modified ^{125}I-HMWKa to kaolin. The binding of ^{125}I-HMWKa to kaolin or butanedione-modified ^{125}I-HMWKa was performed according to the procedure of Scott et al.[9]

Antiserum against HMW kininogen. Antiserum against HMW kininogen was raised by immunizing rabbits with HMW kininogen that had been emulsified with complete Freund's adjuvant. Pooled antiserum was rendered monospecific by successive absorption with plasma deficient in HMW kininogen. Purified antiserum showed one precipitin line against HMW kininogen in normal plasma and no reaction with HMW kininogen-deficient plasma by either immunodiffusion[19] or immunoelectrophoresis.[20]

Measurement of prekallikrein–HMW kininogen complexes When prekallikrein is electrophoresed into agarose containing anti-kallikrein antibody, using the method of Laurell,[21] it fails to migrate at pH 8.6, since it is at or near its isolectric point.[22] On addition of HMW kininogen to the purified prekallikrein, "rockets" of successively increasing height are observed, representing prekallikrein–HMW kininogen complexes of anionic mobility. The height of the rocket is proportional to the concentration of HMW kininogen added.[22]

RESULTS

Time and concentration dependencies of modification of HMW kininogen. Butanedione reacts with the guanido groups of arginine and does not affect the ε-amino group of lysine.[15] When HMW kininogen was modified with butanedione, progressive loss of coagulant activity resulted The loss of coagulant activity at various concentrations of butanedione, as expected, followed pseudo-first-order kinetics when performed at excess reagent concentration (Fig 1). The pseudo-first-order reaction rate constant was proportional to butanedione concentration (Fig 1, insert). The calculated second-order rate constant (k) was 3 × 10^6 (mol/L)$^{-1}$ min^{-1}. When butanedione was immediately mixed with HMW kininogen prior to assay, no effect on the coagulant activity was observed, indicating that butanedione itself was not inhibiting the coagulation assay.

The total number of arginine residues in HMW kininogen is 35/mol,[11] representing 3.5% of the total amino acid residues. The number of arginine residues modified and the percentage of coagulant activity remaining are presented in Table 1. For convenience, four species of modified proteins are distinguished. The coagulant activity of butanedione-modified HMW kininogen decreased about 25% when 2 to 3 arginine residues were modified [BD-HMWK (I)]. When one additional arginine residue was modified, the coagulant activity decreased another 15% [BD-HMWK (II)] Further modification of 2 to 3 arginine residues decreased the coagulant activity to about 40% of the original level [BD-

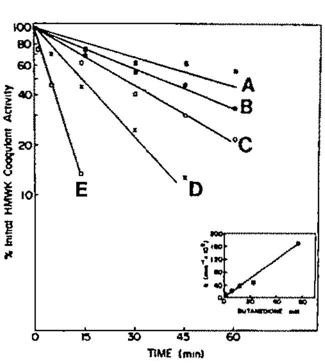

Fig 1. Effect of butanedione modification on HMW kininogen coagulant activity. Purified HMW kininogen was incubated with various concentrations of butanedione. At various times, a portion was assayed for HMW kininogen coagulant activity. The insert shows the concentration dependence of the pseudo-first-order reaction rate from which the second-order rate constant can be calculated. Butanedione concentrations: A, 1.15 mmol/L, B, 5.75 mmol/L; C, 11.5 mmol/L; D, 23 mmol/L; E, 57.5 mmol/L.

Table 1. Effect of Butanedione Modification on the Coagulant Activity of HMW Kininogen

Sample	Arginine Residues Modified*	Specific Coagulant Activity (U/mg)	Percentage of Original Activity
HMW kininogen	0	23.0	100
BD-HMWK (I)†	2.7	17.0	74
BD-HMWK (II)	4.1	14.0	61
BD-HMWK (III)	6.6	8.70	38
BD-HMWK (IV)	17.1	.91	4

*Determined by loss of arginine on amino acid analysis.

†Four levels of modified HMW kininogen were selected, designated BD-HMWK (I)–(IV).

HMWK (III)]. The loss of coagulant activity was directly proportional to the number of arginines modified, up to at least 6.6 residues (Table 1). When almost all of the coagulant activity was lost, about half of the total 35 arginine residues had been modified [BD-HMWK (IV)].

Effect of butanedione modification of HMW kininogen on cleavage by kallikrein. The release of bradykinin by plasma kallikrein involves cleavage of HMW kininogen at lysine-arginine and arginine-serine bonds.[23] Thus it seemed that modification of arginine might affect the cleavage, as assessed by the rate of bradykinin release.

The release of bradykinin from unmodified HMW kininogen by plasma kallikrein gave similar results to those previously reported by Scott et al[9] (Fig 2). Bradykinin was rapidly released from the HMW kininogen by plasma kallikrein during the first 60 minutes and was complete by 120 minutes. After modification with butanedione, however, bradykinin was released at a slower rate. When 2.7 arginine residues were modified [BD-HMWK (I)], bradykinin was slowly liberated, reaching 50% of the maximum level at 60 minutes and 80% after 240 minutes of incubation. With more than 4 arginine residues modified, bradykinin was released from HMW kininogen at an even slower rate and reached only 30% [BD-HMWK (II)] and 15% [BD-HMWK (III) and (IV)] of the control value after 240 minutes of incubation. These results were confirmed by SDS-PAGE analysis of kallikrein digestion of HMW kininogen (120-kDa) to the 65-kDa heavy chains and the 56-kDa and 45-kDa light chains.[9] Although the intact 120-kDa molecule was completely cleaved by 15 minutes in unmodified HMW kininogen, the digestion was slower and traces of the intact molecule persisted at 60 minutes in BD-HMWK (I). In the remaining three modified forms with 4.1, 6.6, and 17 arginines modified, virtually no cleavage of the 120-kDa parent molecule was evident (data not shown).

Butanedione modification of kallikrein-cleaved HMW kininogen. When HMW kininogen was cleaved with plasma kallikrein (HMWKa) prior to incubation with butanedione, it lost coagulant activity at a slower rate than that observed with the intact molecule. The time course of modification of both intact HMW kininogen and HMWKa at two different butanedione concentrations (11.5 mmol/L and 57.5 mmol/L) is shown in Fig 3. HMWKa was more resistant to the butanedione-induced loss of coagulant activity than the intact HMW kininogen. Five times more butanedione was required to inactivate HMWKa than to inactivate the intact procofactor, HMW kininogen. The second-order inactivation rate constant was calculated to be 5.2×10^5 $(\text{mmol/L})^{-1}$ min^{-1} for HMWKa, as compared to the value of 3×10^6 $(\text{mmol/L})^{-1}$ min^{-1} for intact HMW kininogen. Although the rate of modification of HMWKa by butanedione (as reflected by the loss of coagulant activity) was decreased, the extent of modification was not affected. Since HMWKa was modified with butanedione over extended time periods, amino acid analysis showed that 15 arginine residues had been modified. Since bradykinin, which contains 2 arginine residues, was no longer attached to HMWKa, this value agrees with that of 17 arginine residues modified in BD-HMWK (IV).

Binding of butanedione-modified HMWKa to kaolin. The role of arginine residues in the binding of HMW kininogen to a negatively charged surface was studied by

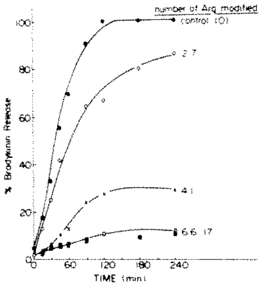

Fig 2. Effect of butanedione on kallikrein-induced bradykinin release from HMW kininogen. HMW kininogen was incubated with butanedione, and the number of arginine residues modified was determined by amino acid analysis (see Methods). HMW kininogen (40 μg), either unmodified or modified to different extents, was incubated with plasma kallikrein (1.4 μg) in a final volume of 300 μL. At various times, a 10-μL portion was transferred to a tube containing 1 μg SBTI. Bradykinin release was determined on each sample.[17] The data are expressed as percent of maximal bradykinin released. Arginine residues modified: ●, unmodified; ○, 2.7 x, 4.1; □, 6.6; ■, 17.

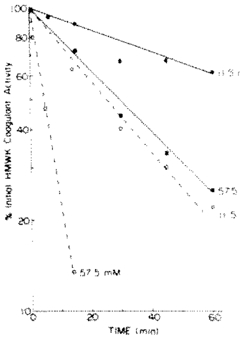

Fig 3. Effect of butanedione on the coagulant activity of cleaved and uncleaved HMW kininogen. Procofactor (HMW kininogen, ---) or active cofactor (HMWKa, ——) was incubated with either 11.5-mmol/L butanedione (●, ○) or 57.5-mmol/L butanedione (■, □). At various times, a portion was assayed for HMW kininogen coagulant activity. The data are expressed as percent of initial HMW kininogen coagulant activity on a semilogarithmic plot.

comparing the binding of unmodified and modified ^{125}I-HMWKa to kaolin. Since intact HMW kininogen binds poorly, if at all, to kaolin[9] and modification with butanedione prevents cleavage, HMW kininogen was cleaved with plasma kallikrein prior to incubation with butanedione. ^{125}I-BD-HMWKa (IV), with 15 arginine residues modified, reached the same saturation point as unmodified ^{125}I-HMWKa (Fig 4). However, about ten times more BD-HMWKa (IV) was needed to achieve the same degree of binding, as compared to the unmodified HMWKa.

Immunochemical analysis of butanedione-modified HMW kininogen. In order to determine whether arginine residues were located in the immunogenic sites of HMW kininogen, antiserum against native HMW kininogen was employed. The results of double diffusion analysis are shown in Fig 5. All modified HMW kininogen samples showed lines of complete identity with unmodified HMW kininogen. These results indicated that arginine residues in HMW kininogen do not critically influence antigen-antibody interaction.

Effect of butanedione modification of HMW kininogen on its complex-formation ability with prekallikrein. HMW kininogen was incubated with butanedione until 90% of the initial coagulant activity was destroyed. This material, or unmodified HMW kininogen, at various concentrations, was mixed with a fixed amount of prekallikrein. These samples were then subjected to electroimmunodiffusion.[22] Both the modified and unmodified HMW kininogen samples were able to increase the height of prekallikrein "rockets" to the same degree as a function of concentration (data not shown). Since this assay is a direct measure of ability to form a complex with prekallikrein,[22] this observation indicates that the loss of coagulant activity of HMW kininogen after modification by butanedione was not the result of the loss of the ability of HMW kininogen to form a complex with the contact system zymogen.

DISCUSSION

Modification of arginine residues of HMW kininogen decreased its coagulant activity (Fig 1) similar to previous observations of two other contact system proteins.[23] By increasing the concentration of butanedione used or by prolonging the reaction time, the coagulant activity of HMW kininogen could be destroyed completely (Fig 1 and Table 1). At least three potential functions of arginines in HMW kininogen may contribute to coagulant activity. First, the positively charged arginine residues may be required for binding to a negatively charged activating surface, and thus their destruction would directly impair the coagulant activity. While this effect is important, this chemical modification alters more than just surface binding. When HMW kininogen was first cleaved by kallikrein to HMWKa and then modified with butanedione, the loss of coagulant activity decreased about fivefold, as judged from the decrease of the pseudo-first-order reaction rate constant (Fig 3). If arginine residues were the only amino acid residues responsible for binding, the cleavage by kallikrein might further expose these residues and the modification with butanedione would have destroyed the activity more quickly rather than more slowly. A second possibility to be considered is that modification of arginine residues impaired the ability of HMW kininogen to form a complex with prekallikrein, since such complex formation is essential for proper alignment of prekallikrein on a negatively charged surface for subsequent cleavage by factor XIIa. However, no impairment of complex formation was found on electroimmunodiffusion. A third possibility is that the loss of coagulant activity is due to the prevention of the cleavage of HMW kininogen by kallikrein, which is necessary for binding to a negatively charged surface.[9] The 2 arginine residues in the nonapeptide bradykinin were apparently modified during the early stage

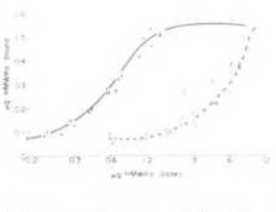

Fig 4. Effect of butanedione modification on the binding of ^{125}I-HMWKa to kaolin. ^{125}I-HMWKa was added to nonlabeled HMWKa. An aliquot was modified with butanedione. Various amounts of either the unmodified (x) or modified (O) HMWKa mixtures were added to microcentrifuge tubes containing 100 μg of kaolin, 300 μg of human serum albumin, and 300 μg of purified fibrinogen in a final volume of 100 μL. After 5 minutes at 25 °C, the samples were centrifuged and the supernatants and pellets were counted for radioactivity.

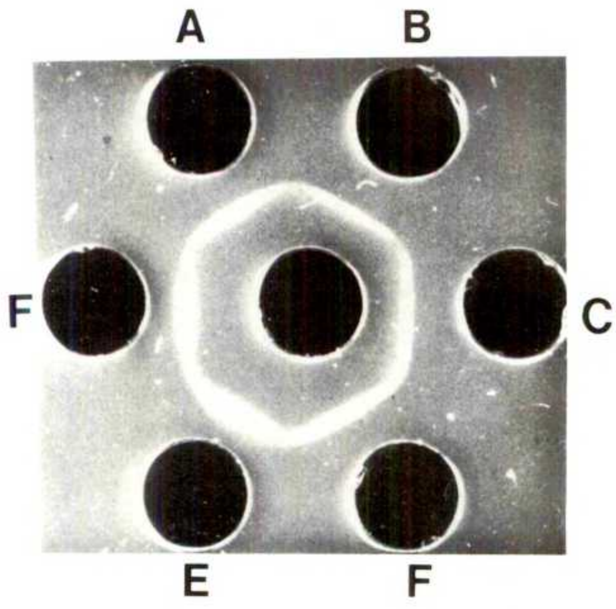

Fig 5. Double immunodiffusion of butanedione-modified and unmodified HMW kininogen. Immunodiffusion was performed in 1% agarose, pH 8.6. The center well contained 20 μL of monospecific antiserum to HMW kininogen. A, D, HMW kininogen unmodified; B, 68% coagulant activity remaining; C, 41% coagulant activity remaining; E, 31% coagulant activity remaining; F, 24% coagulant activity remaining. After the precipitin lines were formed (after 48 hours), the agarose gel was soaked in 0.1 mol/L sodium phosphate, pH 7.0, containing 0.5 mol/L NaCl in order to remove unbound protein. After drying the gel, the protein bands were stained with Coomassie brilliant blue R-250.

of reaction with the protein. Evidence for the modification of these 2 arginine residues was the prevention of cleavage of modified HMW kininogen and the decrease in the release of bradykinin upon incubation with plasma kallikrein (Fig 2). With 2.7 arginine residues modified, plasma kallikrein could still cleave the modified HMW kininogen and release bradykinin from the molecule, only at a slower rate than from an unmodified molecule. However, when more than 4.1 arginine residues were modified [BD-HMWK (II) through (IV)], the cleavage by plasma kallikrein was almost completely prevented, as assessed by SDS-PAGE. Furthermore, bradykinin release was drastically reduced as well (Fig 2). These results suggested that the arginine residue in the lysine-arginine bond in HMW kininogen and the arginine residue of the arginine-serine bond, which must both be cleaved to release bradykinin, are most likely the third and fourth arginines modified. In human HMW kininogen, the arginine-serine bond of bradykinin is first cleaved by kallikrein to generate the 65-kDa heavy chain and the 56-kDa light chain. Further cleavage of the lysine-arginine bond in the COOH terminal of the 65-kDa heavy chain releases bradykinin.[11] The results of butanedione modification also suggested that these 2 arginine residues were located on the surface of the HMW kininogen molecule, as would be expected.

Binding of butanedione-modified HMW kininogen to a model negatively charged surface, kaolin, showed that modification of arginine residues affected the affinity of the molecule to bind to kaolin but not the number of molecules bound (Fig 4). For example, at 1.2 μg HMWKa added, tenfold less modified HMWKa (.05 μg) was observed to bind to kaolin, compared to the binding of unmodified HMWKa (.5 μg). However, the modified HMWKa reached the same extent of binding (.5 μg), albeit at higher amounts added (12 μg) than the unmodified HMWKa. These results suggest that arginine residues influence the affinity of HMW kininogen for negatively charged surfaces, such as kaolin, although they are not absolutely required for binding.

Immunoprecipitation experiments showed that modification of arginine residues did not affect the immunochemical properties of the HMW kininogen molecule (Fig 5). All four modified HMW kininogens, BD-HMWK (I) through (IV), showed lines of complete identity with unmodified HMW kininogen These results indicate that the arginine residues modified are not located in the immunogenic regions of the HMW kininogen molecule.

Thus the mechanism responsible for the inhibition of coagulant activity of HMW kininogen, after modification of arginine groups, appears to be the result of prevention of cleavage of the intact HMW kininogen molecule, which is required to convert it from a procofactor to an active cofactor,[9] as well as a decreased affinity of the active cofactor for the surface.

ACKNOWLEDGMENT

We wish to thank Dr A. David Purdon for performing bradykinin determinations and Dr Linda Knight and Monica Kollman for radiolabeling the HMW kininogen.

Mixed Hematologic Chimerism After Allogeneic Marrow Transplantation for Severe Aplastic Anemia Is Associated With a Higher Risk of Graft Rejection and a Lessened Incidence of Acute Graft-Versus-Host Disease

By Roger S. Hill, Finn Bo Petersen, Rainer Storb, Frederick R. Appelbaum, Kris Doney, Steven Dahlberg, Robert Ramberg, and E. Donnall Thomas

Ninety-six patients with severe aplastic anemia who received a sex-mismatched, HLA-identical allogeneic sibling marrow transplant had sequential cytogenetic analyses performed to determine the incidence and implications of posttransplant mixed hematologic chimerism. Of the 96 patients, 56 (58.3%) became mixed chimeras with coexisting host and donor cells detected in peripheral blood or marrow 14 days or later after transplant, and 40 patients (41.7%) were complete chimeras with 100% donor-type hematopoietic cells. The incidence of mixed chimerism was independent of prior blood production transfusions and infusion of donor buffy coat. The rejection rate was significantly increased in the mixed chimeric group, particularly in patients not receiving buffy coat (14 of 36 rejecting), although overall, the majority (69.7%) retained their first graft. Rejection was seen almost exclusively in patients exposed to multiple transfusions before transplantation. If patients who reject their first graft are censored, the overall incidence of grades II through IV acute graft-v-host disease (GVHD) was significantly reduced in those with mixed chimerism. Transfused patients with mixed chimerism in particular were less likely to develop grades II through IV acute GVHD. The incidence of chronic GVHD was similar in the two groups and did not significantly influence survival. In this study, mixed chimerism persisted for up to 395 days posttransplant, either the first graft being rejected or, more commonly, hematopoiesis reverting to 100% donor-type cells. Mixed lymphohematopoietic chimerism may persist in patients with aplastic anemia who have received matched allogeneic marrow transplants for significant periods before hematopoiesis reverts to donor cell type.

STUDIES OF BLOOD genetic markers including karyotyping, immunoglobulin allotypes, red and white blood cell enzymes, restriction enzyme fragment-length polymorphism, and red blood cell antigens[1-4] are useful after allogeneic marrow transplantation in establishing the presence of donor- or host-type cells in recipients and thus evaluating the outcome of engraftment. Cytogenetic studies of cells from blood and marrow after sex-mismatched, HLA-matched sibling allogeneic transplantation have proved particularly revealing in patients with aplastic anemia. Disappearance of donor-type and reappearance of host-type cells following allogeneic marrow transplantation for severe aplastic anemia have been associated with marrow graft rejection and, most commonly, the return of the original disease or, rarely, complete recovery of autologous marrow function.[5-14] Even more rarely, donor and recipient cells may coexist (mixed chimerism) for many months.[15] However, the overall frequency of mixed chimerism following allografting for severe aplastic anemia and the implications of mixed chimerism for the outcome of the procedure remain to be established.

In the present studies, we have reviewed sequential cytogenetic analyses of marrow and peripheral blood cells in 96 patients with aplastic anemia given marrow transplants from sex-mismatched, HLA-identical siblings after cyclophosphamide conditioning. The frequency and stability of mixed chimerism have been assessed, and the clinical implications—graft rejection, autologous recovery, or sustained allogeneic engraftment—determined.

MATERIALS AND METHODS

Between July 1970 and June 1984, 244 patients were transplanted for severe aplastic anemia. Of them, 125 (51.2%) were sex-mismatched. Nine of the 125 patients were excluded from analysis because of lack of cytogenetic data, including 4 patients who died within 14 days of transplantation before postgraft cytogenetic analyses were performed Two of the remaining 112 patients had HLA-mismatched transplants, and a further 14 received total body irradiation (TBI) as part of the initial preparatory regimen and were also excluded. A total of 96 patients conditioned with cyclophosphamide, 50 mg/kg IV on each of four successive days, and given HLA-identical sibling transplants were therefore eligible for study. All patients were advised of procedures and attendant risks, in accordance with institutional guidelines, and gave informed consent. Tables 1 and 2 show patient characteristics.

The HLA identities of donor and recipient were determined by serologic histocompatibility typing and mixed leukocyte culture (MLC).[5,7,16] The response in MLC of the patient's cells to sibling cells was compared to their response to pooled freshly drawn cells from two unrelated donors or cryopreserved cells from three unrelated donors and then expressed as a ratio, the relative response index, RRI.[17,18] On the basis of data from 212 healthy HLA-identical siblings, a positive relative response was defined as >2.6% and a negative one was <2 6%. The average relative response in this control was 0.0% (two standard deviations = 2 6%) A positive relative response was interpreted to be the expression of transfusion-induced sensitization of the patient against the donor marrow Details of the methods of assessing allogeneic engraftment by cytogenetic analysis and quinacrine dihydrochloride banding of marrow and peripheral blood cells have been described [1,19] Hematopoietic cells for cytogenetic analysis were collected from either

Two groups of patients were identified. The first group, designated "mixed chimeras," consisted of 56 patients in whom cytogenetically proven host and donor hematologic cells coexisted in either bone marrow or peripheral blood at 14 days or later after the first transplant. A second group of 40 patients, designated "complete chimeras," were comparable patients (Table 1) in whom exclusively donor hematopoietic cells were detected posttransplant.

Statistical analysis. Estimation of survival and the probability of developing grades II throught IV acute graft-*v*-host-disease (GVHD) were calculated using the Kaplan-Meier method.[21] Cox regression models[22-24] incorporating time-dependent covariates indicating chimeric status at each time after transplant were used to examine possible associations of chimeric status with survival and acute GVHD incidence. The score test statistic from the Cox model was used to test the hypothesis of no difference between the mixed

RESULTS

Of 96 evaluable patients, 56 (58.3%) with severe aplastic anemia who received an HLA-matched, sex-mismatched marrow transplant became mixed hematologic chimeras with host and donor cells coexisting for some period of time after transplant. Forty (41.7%) were complete chimeras with only donor cells present. The median time for detection of mixed chimerism was 18 days posttransplant (range, 14 to 68 days). Initial detection was made from phytohemagglutinin (PHA)–stimulated blood in 36 patients and from marrow in 20 patients. Thirty-five of 56 mixed chimeric patients (62.5%) had 100% donor metaphases by median day 54 (range, 17 to 395 days). The average number of cytogenetic studies performed on each patient between days 14 and 54 was 5.5 (range, 2 to 12), each study representing a different time point posttransplant. Table 1 shows some clinical characteristics of the 56 mixed chimeric and 40 complete chimeric patients analyzed. The respective male-to-female ratio of 33:23 and 25.15, patient median and age ranges of 21 (2 to 53) years and 18 (3 to 53) years, and donor age and pregraft transfusion histories were comparable for the mixed and complete chimeric groups (Table 1). Eleven mixed chimeric and 9 complete chimeric patients received no transfusions of blood products pretransplant. One of 20 untransfused patients rejected the graft and underwent autologous recovery.

The marrow nucleated cell dose received for the first transplant by 56 patients who subsequently developed mixed chimeras was 4.10 × 10^8/kg recipient body weight and 2.89 × 10^8/kg for 40 patients with complete chimerism (not significantly different).

The relationship between prior blood product transfusion and subsequent development of mixed chimeras was evaluated by analysis of the results of RRI for 40 mixed and 30 complete chimeras. Thirteen mixed and three complete chimeric patients had a positive RRI, not significantly different.

Graft rejection. Seventeen patients with mixed chimerism (30.4%) and two with complete chimerism (5.0%) rejected their marrow grafts (Table 2). This difference in rejection rates between the groups is significant (P = .01). Two mixed chimeric patients who rejected their first marrow underwent complete autologous bone marrow recovery.

Patient survival. The clinical outcome is summarized in Table 2. Twenty-three mixed chimeras (41.1%) and 15 complete chimeras (37.5%) died following transplantation. The median day to death in the mixed chimeric group was 72 (range, 39 to 726) and among the complete chimeras, 82 (range, 8 to 714). More than 50% of the 33 surviving mixed chimeric patients have been followed for more than 5.2 years after transplant, and more than 50% of the 25 surviving complete chimeras have been followed for over 5.9 years. The probability of survival for all patients, including those who rejected their first graft, is presented in Fig 1. No significant differences were found between mixed and complete chimeric patients when using a Cox model to adjust for the time at which mixed chimeric status was determined. The Kaplan-Meier estimate of 5-year survival was 62% for complete and 55% for mixed chimeric patients. Figure 2 shows a similar set of curves when patients who rejected their first grafts were excluded from the analyses. The projected survival advantage for the mixed chimeric group is not, however, significant after adjusting for the time of determination of mixed chimeric status (P = .4). The estimated 5-year survival of patients who sustained their first graft was 62% and 70% for the complete and mixed chimeric groups, respectively, with no deaths occurring past 4 years posttransplant.

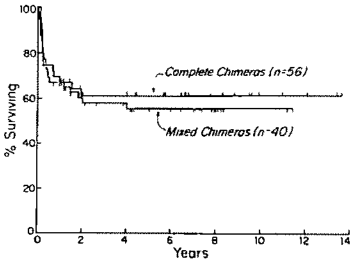

Fig 1. Kaplan-Meier estimates of survival in mixed chimeric and complete chimeric patients, including patients who rejected their first graft. The estimated 5-year survival was 62% for complete and 55% for mixed chimeric patients, not significantly different.

Graft-Versus-Host Disease (GVHD). The incidence and severity of acute GVHD is shown in Table 2. A total of 77 patients—39 mixed and 38 complete chimeras who achieved durable engraftment without rejection—were evaluable for acute GVHD. In the mixed chimeric group, 30 patients had no acute GVHD and 9 developed acute GVHD, including 2 with grade I and 7 with grades II through IV GVHD. Fourteen complete chimeric patients had no acute GVHD and 24 developed acute GVHD, including 4 with grades I and 20 with grades II through IV. The difference in the incidence of acute GVHD grades II through IV between the two groups was significant (P = .03), using the score test from the Cox model. When patients who were tranfused before transplantation were analyzed separately, 3 of 29 mixed chimeras but 17 of 29 complete chimeras developed grades II through IV acute GVHD. This difference in incidence between the groups is highly significant (P =

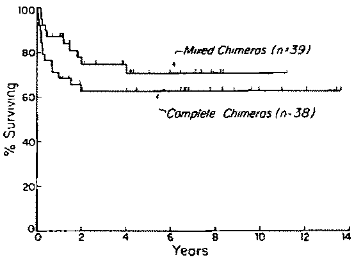

Fig 2. Kaplan-Meier estimates of survival in mixed chimeric and complete chimeric patients, excluding patients who rejected their first graft. The estimated 5-year survival was 62% for complete and 70% for mixed chimeric patients, not significantly different.

.002). The small numbers of untransfused patients (Table 1) precluded a similar acute GVHD analysis The Kaplan-Meier estimate of the probability of developing grades II through IV acute GVHD for mixed chimeric and complete chimeric groups is depicted in Fig 3. The curves are significantly different, showing an increase in the frequency of acute GVHD in the complete chimeric group. By 2 months posttransplant, the incidence of grades II through IV acute GVHD is projected as 18% for the mixed chimeric group and 57% for the complete chimeric groups ($P = .03$, adjusting for the time of determination of mixed chimeric status). Four of 7 mixed chimeras with grade II through IV acute GVHD are surviving, compared with 8 of 20 complete chimeras.

Chronic GVHD. The incidence of chronic GVHD in patients censored for rejection was 15 of 39 in the mixed chimeric group and 18 of 38 in the complete chimeric group (not significantly different; Table 2). Comparable numbers of patients, 9 of 15 and 9 of 18 in the mixed and complete chimeric groups with chronic GVHD, had previously received buffy coat. Ten of 15 mixed chimeric patients with chronic GVHD, including 6 of 9 who received buffy coat and 4 of 6 who received no buffy coat, are survivors. By comparison, 12 of 18 complete chimeric patients with chronic GVHD are surviving, including 6 of 9 who received buffy coat and 6 of 9 who did not. The incidence of chronic GVHD did not significantly influence the survival in these groups.

Donor buffy coat infusion. Twenty of 56 patients (35.7%) with mixed chimerism and 12 of 40 (30%) with complete chimerism had received viable donor buffy coat infusions following transplantation. The effect of receiving buffy coat on graft rejection was evaluated. Three of 20 (15%) mixed chimeras who received buffy coat rejected their grafts and 2 are surviving, both following a second allogeneic graft. Fourteen of 36 (38.9%) mixed chimeric patients who received no buffy coat rejected their grafts and 2 are surviving, both following autologous hematologic recovery. By comparison, 0 of 12 complete chimeras who received buffy coat and 2 of 28 (7.6%) complete chimeric patients who received no buffy coat rejected their grafts. Using a two-sided Fisher's exact test, the difference in rejection rates between mixed and complete chimeric patients not receiving buffy coat is significant ($P = .008$), as is the overall difference in incidence of rejection in the mixed and complete chimeric patient groups.

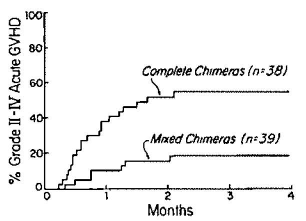

Fig 3. Probability of developing Grades II through IV acute graft-*v*-host disease in complete and mixed chimeric patients. The incidence at 2 months posttransplant is projected as 18% for mixed chimeric and 57% for complete chimeric groups. Significance ($P = .03$) was obtained from a Cox regression model incorporating the time of determination of mixed chimeric status

DISCUSSION

In this study we have demonstrated that a majority (58.3%) of patients transplanted for severe aplastic anemia had evidence of coexisting host and donor hematopoietic cells (mixed chimerism) 14 days or longer after transplantation. The presence of mixed chimerism appeared to be independent of whether or not patients had multiple transfusions before transplant and independent of the use of viable donor buffy coat infusions to ensure engraftment. Patients who were mixed chimeras had a significantly higher rate of graft rejection, 17 of 56 (30.4%), than patients who were complete chimeras, 2 of 40 (5.0%). As a rule, rejection was seen in patients exposed to multiple transfusions before transplantation, suggesting that it was mediated by specifically sensitized host immune cells. Most mixed chimeras (69.2%) did not reject their grafts, and host cells tended to disappear by a median time of 54 days with occasional persistence beyond 1 year. No patient remained a mixed chimera beyond 395 days; by that time patients had either rejected their first graft or converted to complete chimerism.

Only one patient has been reported in the literature to have established long-term stable mixed chimerism after matched allogeneic marrow grafting for aplastic anemia.[15] Our findings suggest that as a rule, surviving host-cells in mixed chimeras are ultimately replaced either as a result of immunologic or competitive removal by donor cells or because host pluripotent stem cells generally lack sustained proliferative capacity to provide durable hematopoiesis, a feature of the original aplastic anemia. This lack of stable mixed chimerism in patients with severe aplastic anemia is distinct from that of dog and rhesus monkey models. Previous animal studies have shown that cyclophosphamide[25-27] and dimethyl myleran[28] can be used instead of total body irradiation (TBI) to prepare recipients for successful marrow engraftment. These chemotherapy chimeras, in contrast to radiation chimeras, rather commonly show a persistent mixture of host and donor lymphopoietic cells in long-term survivors who did not subsequently reject their graft.

Failure of donor marrow engraftment with subsequent autologous recovery has been rarely reported in patients with aplastic anemia.[10-15,29] In most of these patients, cytogenetic studies were not used to confirm the coexistence of donor and host hematopoietic cells prior to rejection. Two of our mixed chimeric patients showed complete autologous recovery, and it may have been the intrinsic ability to recover from severe aplastic anemia that first led to mixed chimerism and then to a gradual displacement of the graft.

A second major finding of the present study is that, censoring for graft rejection, patients with mixed chimerism who maintained their first grafts had a significantly reduced incidence of grade II through IV acute GVHD.

The precise mechanisms leading to mixed chimerism and to the avoidance of acute GVHD in our patients are unknown. A likely explanation is that elimination of host cells requires both the cytotoxic effects of the preparative regimen (in this case cyclophosphamide) and the immunologic reaction of allogeneic donor T cells against residual host immune cells. Donor cells that are more closely matched for non-HLA antigen with the patient may not be able to eradicate host cells, and therefore the persistence of mixed chimerism may be evidence of closer tissue matching between host-donor pairs. Less GVHD in this setting would therefore be expected. Similarly, donor cells associated with less vigorous immune response genes may be less able to eradicate residual host cells, and less GVHD might also be expected in this setting.[30,31] In either case, the inability of donor cells to eradicate host cells would likely allow a rebound in host immunity and therefore an increased risk of graft rejection. Alternatively, persistent host cells might in some way actively suppress donor reactivity against the host. The precise way in which this might occur is unclear but could involve either active suppression or elimination of donor clones by persisting or reemerging host cells.[32] In this clinical setting, the issue of whether putative minor antigens responsible for GVHD might be the same as or different from those responsible for rejection is unresolved.

The observations and conclusion in this study are limited to sex-mismatched donor-recipient combinations prepared for transplantation without TBI since identification of donor-host origin is simplest and most accurate in this setting. We have also limited our analysis to patients prepared for transplant with cyclophosphamide. In the few transplants we have performed for aplastic anemia with TBI, mixed chimerism was seen only once, presumably due to the more intensive immunosuppressive preparative regimen.

We have previously observed that recurrent leukemia is seen less often posttransplant in patients with significant GVHD than in recipients of allogeneic marrow who do not develop GVHD.[33] This observation has been interpreted to mean that one of the targets of the GVH reaction is host leukemic cells. An alternative explanation for the graft-*v*-leukemia effect compatible with the data presented here is that persisting leukemic cells, alone or with other host elements, are themselves capable of suppressing the GVH reaction. Ultimately it will be essential to understand these phenomena more completely since they may provide methods for preventing GVHD and insights into how donor-host reactivity may or may not be manipulated to aid in the treatment of aplastic anemia and leukemia.

Treatment of Hairy Cell Leukemia With Recombinant Alpha Interferon: I. Quantitative Study of Bone Marrow Changes During the First Months of Treatment

By Georges Flandrin, François Sigaux, Sylvie Castaigne, Christian Billard, Michel Aguet, Michel Boiron, Ernesto Falcoff, and Laurent Degos

Seventeen patients with hairy cell leukemia (HCL) were treated with low doses of recombinant alpha interferon (IFN) for over 4 months. Marked improvement was observed in peripheral blood and bone marrow in 15 of 17 patients. Comparison of pretreatment values and hemograms obtained after 4 months of treatment showed a marked decrease in circulating hairy cells ($P < .01$), a decrease in the number of lymphocytes ($P < .01$), a rise in the number of platelets ($P < .05$), granulocytes ($P < .05$), and monocytes ($P < .01$), and a rise in the hemoglobin level ($P < .01$). Transient reduction in the number of granulocytes was noted during the first month. Correction of thrombocytopenia often appeared within 2 months and usually preceded improvement of anemia, monocytopenia, and neutropenia. Bone marrow biopsy specimens were taken before treatment and 2, 4, and 7 months after its initiation. The volumes occupied by hairy cells, cells of the myeloid lines, and adipocytes were studied by stereological analysis of semithin sections. Decrease in the volume occupied by hairy cells was seen after 4 months of treatment ($P < .01$), and the volume continued to decrease at the seventh month ($P < .05$). Hairy cells were no longer detected on bone marrow biopsies of 4 of 17 patients by the fourth month and in 3 of 8 additional patients by the seventh month. A rise in the volume occupied by normal myeloid cells was visible by the second month of treatment ($P < .01$). Nevertheless, the volume occupied by granulocytes remained lower than in the normal controls ($P < .01$). After an initial increase during the first 2 months of treatment ($P < .01$), the overall cellularity remained unchanged at 4 months and decreased significantly ($P <$ .05) at 7 months. Except for biopsies at 2 months, mean cellularity was below that of control biopsies ($P < .01$).

QUESADA ET AL recently demonstrated the efficacy of treating seven cases of hairy cell leukemia (HCL) with partially pure alpha (leukocyte) interferon.[1] They obtained three complete and four partial remissions. In order to test the efficacy of treatment with comparable low doses of recombinant alpha interferon (IFN), we started a clinical trial in May 1984 in which 37 HCL patients were progressively entered. This treatment was evaluated by its effects on both peripheral blood and bone marrow However, fibrosis rendered bone marrow study difficult, and satisfactory investigation could be achieved only by using bone marrow biopsies. There were additional problems of correctly identifying the hairy cells and selecting the method of cell evaluation least subject to sampling error. In order to facilitate hairy cell identification and obtain objective evidence regarding alterations of the bone marrow, semithin sections prepared from biopsy specimens embedded in resin were subjected to stereological analysis.[2] This report is based on 17 patients of our series who received treatment for over 4 months and for whom we monitored the changes in peripheral blood and the volumes occupied by hairy cells, myeloid cells, and adipocytes in bone marrow biopsies both before and 2, 4, and 7 months after initiation of treatment.

MATERIALS AND METHODS

Treatment protocol. In May 1984, a nonrandomized study using subcutaneous injections of recombinant alpha interferon from two different suppliers (alpha$_A$ IFN from Hoffman-La Roche, (Basel, Switzerland), 3 × 10^6 U/d, and alpha$_2$ IFN from Schering Corp., 2 × 10^6 U/m^2 in three weekly injections) was started In September 1984, we also began treating patients with partially purified (leukocyte) alpha IFN 3 × 10^6 U/d. Leukocyte alpha IFN was kindly provided by Dr Cantell (Finnish Red Cross). All patients were advised of procedures and attendant risks in accordance with institutional guidelines and gave informed consent. The initial phase of treatment lasted 7 months. Between May 1984 and March 1985, 37 patients were progressively enrolled in the trial. Thirty one patients were treated with recombinant alpha IFN and six with natural alpha IFN

Patients This report is based on 17 patients for whom treatment with recombinant IFN has exceeded 4 months. Eleven patients had undergone splenectomy at least 6 months previously. Two of the six nonsplenectomized patients did not exhibit splenomegaly prior to treatment; the remaining four patients had splenomegaly of less than 6 cm under the costal margin. Only one patient had prior chemotherapy. Hairy cells were found in the bone marrow of all patients and in the blood of all but one patient. Five patients had hyperleukocytosis (leukocytes > 10 × 10^9/L). Fourteen patients were cytopenic, with decreased levels of hemoglobin (< 12.5 g/dL), granulocytes (< 1 5 × 10^9L), or platelets (< 150 × 10^9/L). Nine patients received alpha$_A$ IFN and eight alpha$_2$ IFN. No significant difference (U test) was found between the two groups as to levels of hairy cells, granulocytes, platelets, or hemoglobin Treatment was discontinued after 4 months for one patient due to total lack of response and for another patient (a woman with a mild form of HCL) because of serious alopecia.

Methods Hemograms and leukocyte counts were done weekly during the first month and at least monthly thereafter. Bone marrow biopsies (BM) were done with a Jamshidi needle in the days immediately preceding treatment and 2, 4, and 7 months after initiation After embedding the specimens in resin (epoxy or glycolmethacrylate), semithin sections (2 μm) were prepared and stained with toluidine blue (Fig 1) or Giemsa. The reticular network was stained by a technique derived from Gomori's method. Stereological analysis (point-counting method) of bone marrow was carried out according to the usual methods,[2] using a Weibel M42 multipurpose grid (objective 100 ×, eyepiece 12.5). For each specimen approxi-

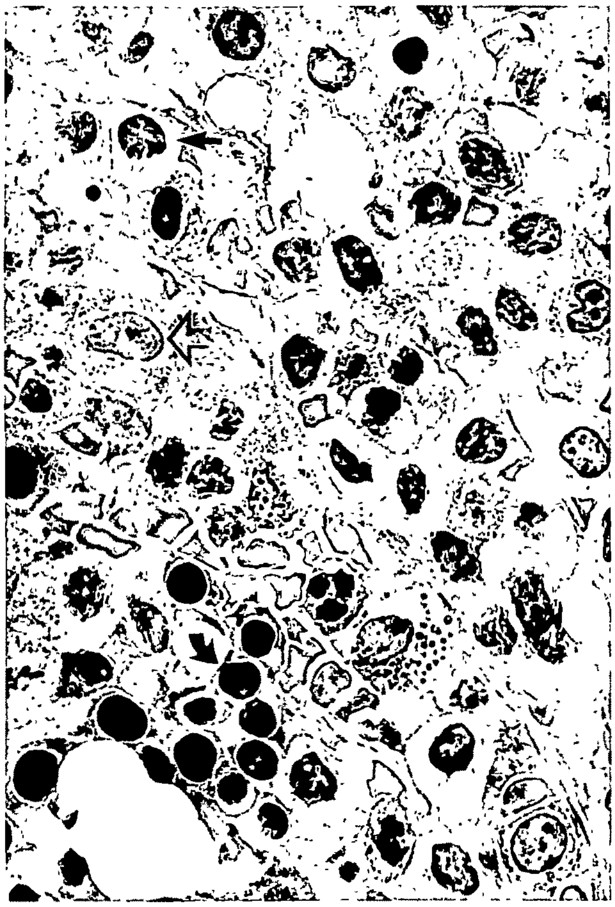

Fig 1. Semithin section of bone marrow biopsy obtained after 4 months of treatment. ←, hairy cells; —→, erythroblasts; ⇐, granulocytes.

mately 1,000 points were counted (1,010 ± 44), giving a probable error of .2%, .3%, .5%, and .7% for the relative volumes (ie, volume density) of 1%, 2%, 5%, and 10%, respectively[2] The analysis was done on randomly selected fields according to a predetermined diagram With counting based on the entire cell (both nucleus and cytoplasm), each cell was classified as one of the following: hairy cell, erythroblast, megakaryocyte, granulocyte, or adipocyte. Lymphocytes, plasmocytes, eosinophils, vascular cells, and unidentifiable cells were grouped together in the category "other cells." Extracellular spaces and other elements of the stroma were also computed As extracellular spaces and fibrosis were obvious in most biopsies, cellularity cannot be defined by reference to adipocytes. We defined cellularity as the sum of hairy cell, myeloid cell, and "other cell" relative volumes Ten normal-appearing marrows were measured as controls (Hodgkins and non-Hodgkins lymphomas without bone marrow infiltration in adults aged 40 to 50 years).

Statistical analysis. Comparisons of the means were tested by Wilcoxon's paired test for paired values and by Mann-Withney's test for unpaired data. Correlations were analyzed by the Spearman correlation test. The P level was set at 5% Data were pooled from patients treated with alpha$_A$ IFN and from those treated with alpha$_2$ IFN For simplicity, both interferons are referred to as IFN in the text.

RESULTS

After 4 months of treatment, we found a decrease in the number of circulating hairy cells ($P < .01$) and lymphocytes ($P < .01$) and a rise in the level of granulocytes ($P < .05$), monocytes ($P < .01$), platelets ($P < .05$), and hemoglobin ($P < .01$). Normalization of anemia (Hb < 12.5 g/dL), granulocytopenia (granulocytes < 1.5×10^9/L), and thrombopenia (platelets 150×10^9/L) was observed, respectively, in 8 of 11, 6 of 12, and 7 of 10 of the initially affected patients. Figure 2 shows the evolution of the mean hematologic values over the first 4 months. During the first month there was a decrease in the number of circulating hairy cells, particularly marked (with the exception of one nonresponder patient) for the hyperleukocytic patients. There was also a transient reduction in granulocytes for all patients during the first month. As shown in Fig 2, in initially cytopenic patients, mean platelet levels increased the first and second months of treatment, while increases in granulocytes and hemoglobin levels were not significant before the end of the second month. The evolution of monocyte levels was somewhat variable, with transient monocytosis commonly cumulating during the third month. In patients who were not initially cytopenic, no significant changes in neutrophil, platelet, or hemoglobin levels occurred after the second month (Fig 2). In the 13 patients who were treated for over 4 months, and results remained good during continued treatment (5 to 7 months) or even improved (five cases).

Hairy cells were no longer detectable in 4 of 17 patients (all treated with alpha$_2$ IFN) after 4 months and in 3 of 8 additional patients (1 treated with alpha$_A$ IFN) after 7 months. All biopsies showed reticular fibrosis. After 4 months of treatment, we observed no clear fibrosis diminution as assessed by conventional morphology. Fibrosis was

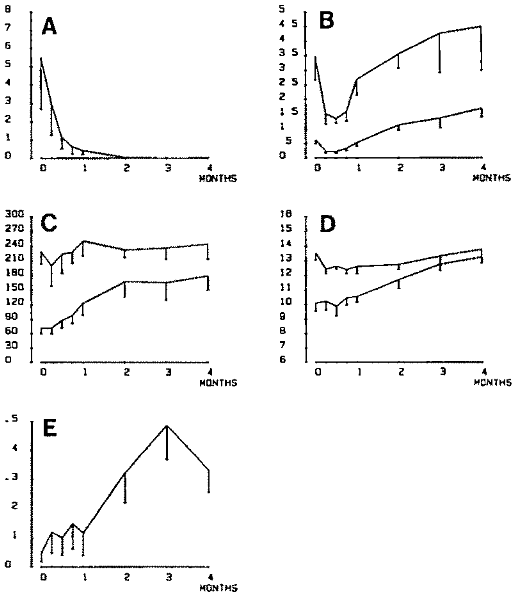

Fig 2. Evolution of hemograms throughout the first 4 months of treatment for the 16 patients with objective responses. (A) HC, hairy cells; (B) PMN, granulocytes; (C) PLT, platelets; (D) HB, hemoglobin; (E) MONO, monocytes. For PMN, PLT, and HB, the lower curve of the graph plots the values for the cytopenic patients and the upper curve those for the noncytopenic patients; cutoffs adopted were PMN, 1.5×10^9/L; PLT, 150×10^9/L, HB, 12.5 g/dL. The plotted points are the means of the parameters; ⊢ is the standard error of the mean (SEM).

always diffuse. In the biopsies showing hairy cell focal invasion, fibrosis seemed greatest in the regions infiltrated by these neoplastic cells. Compared to the initial biopsies, after 4 months all patients showed a significant decrease in the volume occupied by hairy cells ($P < .01$) and an increase in the volumes occupied by cells of the granulocyte ($P < .01$), erythroblast ($P < .01$), and megakaryocyte ($P < .01$) lines No significant changes of volume were found for adipocytes, but a significant increase in overall cellularity ($P < .05$) was observed.

The evolution of the mean stereological parameters is illustrated in Fig 3 A significant decrease ($P < .01$) in the volume occupied by hairy cells was found in month 4 biopsies and became more marked by month 7 ($P < .05$). An increase in the volumes occupied by myeloid cells became distinct by the second month ($P < .01$), but month 4 biopsies showed no further significant change. Month 7 biopsies showed a decrease in the volumes of erythroblasts ($P < .05$), while granulocytic and megakaryocytic cell lines showed no significant changes. The mean volumes occupied by adipocytes remained comparable on initial biopsies and after 2 and 4 months' treatment. By the seventh month, however, an increase was observed in adipocyte volume compared to the month 4 volume for the same patients ($P < .01$). Mean granulocyte volumes, either initially or after 2, 4, and 7 months of treatment (respectively, 2.94 ± 4.79%, 11.12 ± 8.47%, 13.66 ± 8.10%, and 12.86 ± 8.8%) remained significantly ($P <$ 01, U test) below those of controls (26.11 ± 3.68%). This hypoplasia of the granulocytic line was not correlated with the persistence or disappearance of hairy cells and was present in 4 of 7 patients whose biopsies no longer showed any hairy cells The cellularity increased after 2 months ($P <$ 01), remained unchanged after 4 months, and decreased after 7 months ($P < .05$). No statistically significant correlation (Spearman test) was found between platelet, neutrophil blood cell count, hemoglobin level, and BM volumes of megakaryocytic, granulocytic, and erythroblastic series, respectively

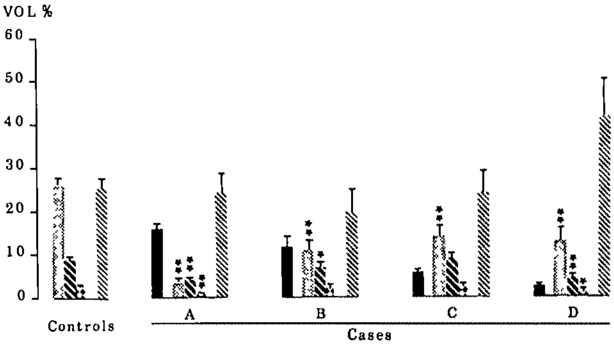

Fig 3. Mean relative volumes occupied by the different constituents of the bone marrow tissue, determined by stereological analysis of semithin sections. Controls: figures for ten bone marrows of normal appearance (see Materials and Methods). Patients: mean volumes (A) before treatment (17 patients), (B) after 2 months of treatment (12 patients), (C) after 4 months of treatment (17 patients), (D) after 7 months of treatment (8 patients). ⊢ is the SEM. ■, hairy cells; □, granulocytes; ▧, erythroblasts; ⊟, megakaryocytes; ▧, adipocytes. The mean volumes for HCL patients were compared with those of the controls (Mann-Withney U test): $^{*}P < .05$, $^{**}P < .01$. Cellularity (as defined in MM) was 22.8 ± 7.6% before treatment, increased ($P < .01$) to 29.7 ± 11.3% after 2 months, remained at 30.0 ± 10.4% after 4 months, and decreased ($P < .05$) to 20.6 ± 11.4% after 7 months of therapy. Cellularity after 4 and 7 months of treatment remained significantly ($P < .01$) below that of the controls (37.8 ± 4.9%).

As a whole, a clear improvement was observed for all but two patients. No improvement was noted for one patient, who was characterized by the presence of hyperleukocytosis, the absence of any myeloid cytopenia with a persistent monocytosis appearing after splenectomy. The response was modest for another patient who had undergone unsuccessful chemotherapy (vinblastine, bleomycin, prednisolone), which was discontinued 1 month prior to treatment with alpha IFN. With the 15 other patients, regardless of the form of alpha IFN administered, distinct improvement of blood, bone marrow, or both was obtained. The splenomegaly present in four patients disappeared during the first 2 months of treatment. It must be stressed, however, that complete normalization of blood and bone marrow parameters (including restoration of myeloid volumes at normal level) were obtained in only one patient. Apparently, splenectomized and nonsplenectomized patients show identical outcomes during the first months of therapy.

DISCUSSION

The management of HCL is still open to controversy. Splenectomy produces improvement of myeloid cytopenias in 30% to 60% of cases and significantly increases survival for patients with severe splenomegaly.[3-5] What remains difficult is the treatment of patients without splenomegaly (28% of 211 cases in our previous series[5]) and of nonresponders to splenectomy (50% in our series). Single-drug therapies, particularly with chlorambucil, often improve anemia and thrombocytopenia but seem to have no effect on neutropenia;[6] the patients remain exposed to infection, which is the most common cause of death and an important prognostic factor[7] Leukapheresis[8] produces only transient improvement. Combination drug therapy is used for the more serious cases (approximately 5% of all cases) and can induce some complete remissions, but at the cost of very high mortality.[10] Quesada's recent demonstration of the efficacy of natural alpha IFN[1] prompted us to start a clinical trial with recombinant alpha IFN for patients with HCL of varying degrees of severity. The unequivocal effects documented in the blood and bone marrow of 15 of 17 patients who were monitored for more than 4 months attest to the rapid action of alpha IFN treatment and are in agreement with results of other concurrent studies.[11-16] Compared to other forms of treatment (other than combination drug therapy), IFN is the only one that achieves the disappearance of hairy cells in the bone marrow in a certain percentage of cases (4 of 17 cases after 4 months and 3 of 8 additional cases after 7 months) and the correction of myeloid cytopenia.

The difficulty of correctly assessing the state of bone marrow during treatment must be stressed. Reticular fibrosis, which interferes with aspiration, persists for several months even after complete remission.[9] Hairy cell infiltration can be studied only by using bone marrow biopsies, and even then, cell identification remains difficult and presents diagnostic problems when the infiltration is moderate. The technique of semithin sections prepared from specimens embedded in resin makes the identification of abnormal cells easier (Fig 1) and permits reproducible stereological studies of the volumes occupied by the different marrow cells. This objective quantitative analysis allows us to establish that the increase in the myeloid cell volumes is rapid, detectable by the end of the second month of treatment. The decline of the hairy cell infiltration generally occurs later, becomes significant only by month 4, and continues to decline until month 7. These results are in contrast with those of the peripheral blood, in which the decrease of hairy cells occurred early, often within the first month, whereas correction of cytopenia (except thrombocytopenia) takes place later, becoming significant only after 3 or 4 months of treatment. The dissociation of blood and marrow results can be observed both at month 4 and at month 7 and compels us to evaluate the treatment by its effects on blood and bone marrow alike.

Quantitative analysis of the biopsies also allows us to show that the volumes occupied by the granulocytic series remained much smaller than in the controls (except for two of 17 cases at month 4 and one additional case of eight at month 7). In addition, 7-month biopsies showed a decrease in cellularity and erythroblast volumes and a clear increase in adipocyte volume. The significance of these findings remains unclear. Both residual disease and interferon therapy may be involved. However, a biopsy represents but a very small fraction of the total marrow. Marrow scans will be performed to search for a peripheral expansion of active hematopoietic marrow. This fact can explain the lack of correlation between blood counts and volumes occupied by the myeloid precursor cells in the bone marrow.

The quality of the clinical results in the long term, the advantage of obtaining complete remission rather than mere normalization of peripheral cytopenias, and the optimum duration of treatment still need to be clarified. Nevertheless, it is already possible to assert that the results obtained to date for the more severe forms (eg, severe pancytopenia with serious recurrent infections: three cases in this study) are of considerable interest since the prognosis without treatment for such patients is poor.[10] Furthermore, the very low growth rate of hairy cells[17] gives us good reason to hope for lengthy remissions for a high proportion of HCL patients.

Treatment of Hairy Cell Leukemia With Recombinant Alpha Interferon: II. In Vivo Down-Regulation of Alpha Interferon Receptors on Tumor Cells

By Christian Billard, François Sigaux, Sylvie Castaigne, Françoise Valensi, Georges Flandrin, Laurent Degos, Ernesto Falcoff, and Michel Aguet

Interferons (IFNs) initiate their effects by interacting with specific high-affinity cell surface receptors, but little is known about the physiology of IFN receptor interaction in vivo. Treatment of patients suffering from hairy cell leukemia (HCL) with human recombinant alpha IFN results in significant tumor regression, with clinical improvement in a high percentage of cases. To investigate a possible relevance of binding parameters as response markers, IFN receptor interaction on tumor cells responsive to IFN in vivo was studied. Binding of human alpha 2 IFN to circulating hairy cells was analyzed before and during IFN therapy in ten patients selected on the basis of high numbers of peripheral hairy cells. Binding experiments were carried out on Ficoll-Paque fractionated peripheral cell samples containing a majority of hairy cells. All patients reacted to recombinant alpha IFN treatment with a striking decrease in binding capacity within 12 hours after the first injection. As demonstrated by using a monoclonal antibody able to recognize alpha 2 IFN bound to its receptor, this decreased binding capacity was not due to blocking by circulating IFN but rather to a decrease in receptor number. This receptor "down-regulation" was partially reversible after the first IFN injection. However, upon prolonged IFN therapy, all patients displayed a stable state of decreased receptor expression. Down-regulation of IFN receptors can be regarded as a response marker to IFN treatment. This response marker, however, was not correlated with the clinical response within the first months of IFN therapy.

© 1986 by Grune & Stratton, Inc.

INTERFERONS (IFNs) are proteins with the common property of protecting cells from viral infection. In addition they exert a variety of pleiotropic effects, such as modulation of various immune functions and inhibition of cell growth.[1-4] Like polypeptide hormones or growth factors, IFN action is initiated by binding to specific high-affinity cell surface receptors.[5,6] IFNs comprise three types (alpha, beta, and gamma), and the alpha type is further subdivided into at least 12 subtypes.[7] While pathways of gamma IFN action seem independent from those of alpha and beta IFN,[8,9] the latter initiate their effects by interaction with presumed common receptors.[9-13] Despite a considerable amount of data on the initial receptor interaction of IFNs and the subsequent steps, including internalization and degradation, major questions on the signal initiated by receptor binding are unresolved. Likewise, the necessity of ligand and/or receptor internalization for interferon action has not been demonstrated unequivocally, and the role of decrease of receptor number induced by IFN binding (called receptor "down-regulation") remains unclear.[5,6,9,14,15] The antitumor potential of IFNs can be mediated by a direct cytostatic action on tumor cells as well as indirectly through stimulation of immune response; in both cases, the mechanisms involved are elucidated only in part.[2] Beyond comparative binding data on various lymphoid cells,[16] little is known as yet on the initial steps of IFN action in vivo. Recently, alpha IFN was reported to induce remission in hairy cell leukemia (HCL).[17] To investigate the role of cell surface receptors as markers for responsiveness of HCL to IFN therapy, IFN binding was studied on tumor cells from HCL patients treated with recombinant alpha IFN. Five of the 17 patients studied in part I of this report and five additional patients who entered the same clinical trial were selected on the basis of high numbers of circulating hairy cells before onset of IFN therapy. Number of receptor sites for alpha IFN and the affinity constant were determined before and during IFN therapy by studying the binding of ^{125}I-labeled human alpha 2 IFN.[10] In addition, the degree of receptor occupation under IFN treatment was studied with a monoclonal antibody that recognizes alpha 2 IFN bound to its receptor.

MATERIALS AND METHODS

Patients and treatment protocol. Experiments were carried out with ten patients with hairy cell leukemia who entered the trial described in part I of this report. The patients were selected on the basis of high number of peripheral hairy cells before onset of therapy (>10 × 10^9 leukocytes/L) Based on peripheral blood and bone marrow data, clinical progress of patients 2, 4, 8, 9, and 21, for whom treatment has exceeded 4 months, is described in part I of this study. All patients were advised of procedures and attendant risks in accordance with institutional guidelines and gave informed consent.

Patients 2, 4, 25, and 29 were treated with daily subcutaneous injections of 3 × 10^6 units of recombinant human alpha 2 IFN (Hoffman-La Roche, Basel, Switzerland). Patients 4, 8, 21, 27, 36, and 38 were treated with 2 × 10^6 U/m^2 of recombinant human alpha 2 IFN (Schering Corp, Kenilworth, NJ) in three weekly subcutaneous injections. These two IFNs differ in only one amino acid[7] and are referred to as recombinant alpha IFN in the following text

Binding assay. Peripheral blood cells, including a majority of hairy cells, were enriched by fractionation on Ficoll-Paque (Pharmacia, Uppsala, Sweden) according to the manufacturer's protocol. The percentages of hairy cells obtained under these conditions for each binding experiment are shown in Table 1. Subsequently, cells were washed three times at 4 °C with Hank's balanced salt solution (HBSS) containing 10 mmol/L HEPES with 10% fetal calf serum (KC Biological, Lenexa, Kan) and resuspended in this buffer at a density of 2 × 10^7 cells/mL. To determine saturation curves, binding experiments were carried out in U-bottomed microtiter plates at a cell density of 10^7 cells/mL (200 μL/well) as described elsewhere[18] All incubations with ^{125}I-labeled human alpha 2 IFN were for 90

HCL patients were treated according to the protocols described in Materials and Methods For each binding experiment, peripheral blood mononuclear leukocytes were fractionated on Ficoll-Paque gradient. Other cells present in these preparations were lymphocytes and occasionally monocytes. ND, not determined

minutes at 4 °C. Specific binding of ^{125}I–alpha 2 IFN was measured at six different IFN concentrations: 10,000, 5,000, 2,500, 1,250, 625, and 300 U/mL. Nonspecific binding was determined by simultaneous addition of 2×10^5 U/mL of unlabeled human alpha 2 IFN. Binding constant (Kd) and number of binding sites were extrapolated by Scatchard analysis of saturation curves as described previously [18]

Since blood samples had to wait for variable periods of time (up to 12 hours) at 4 °C prior to IFN binding experiments, it was important to ascertain the variability of binding data during these intervals. On cells kept at 0 °C to 4 °C in balanced salt solution, receptor expression and binding affinity remained virtually unchanged for periods up to 48 hours. Also, cell fractionation on Ficoll-Paque did not modify the binding data (data not shown)

Mouse monoclonal antibody against human recombinant alpha 2 *IFN* Mouse monoclonal antibodies against human recombinant DNA alpha 2 IFN were raised as described elsewhere.[19] These antibodies were characterized with regard to IFN subtype specificity, neutralization of antiviral activity, and the capacity to recognize human alpha 2 IFN specifically bound to its cell surface receptors.[20] For the indirect binding assay described below, an antibody (I/11) specific for alpha 2 IFN in a solid-phase radioimmunoassay was selected.[19] Although this antibody did not neutralize the biological activity of alpha 2 IFN it was able to recognize alpha 2 IFN specifically bound to its cell surface receptors on human lymphoid Daudi cells pretreated with alpha 2 IFN. Nonspecific binding was determined by simultaneous addition of excess human beta IFN, which binds to the same receptors as alpha IFN[9,12,13] but is not recognized by the monoclonal antibody I/11. Binding of monoclonal antibody I/11 was revealed by addition of an ^{125}I-labeled rabbit antimouse IgG antibody as described below.

Indirect binding assay. Peripheral blood cells were prepared as described above and adjusted to 2×10^7 cells/mL in the same buffer. To detect receptor-bound alpha 2 IFN, the cells were incubated for 90 minutes at 4 °C with the mouse monoclonal antibody (I/11) capable of recognizing alpha 2 IFN specifically bound to its cell surface receptors, which has been described above and elsewhere.[19] Control experiments were carried out with a nonspecific mouse monoclonal antibody (I/0). Cells were then washed twice, and bound mouse antibody was revealed by incubation for 90 minutes at 4 °C with an ^{125}I-labeled rabbit antimouse IgG antibody in the presence of 1% normal rabbit IgG to block Fc receptors. This rabbit antimouse IgG antibody was purified by affinity chromatography on mouse IgG coupled to Affigel-10 (Biorad, Richmond, Calif) and labeled with [^{125}I] sodium iodide (CEA, Gif sur Yvette, France) to a specific radioactivity of 15 to 30 μCi/μg protein. Briefly, 1 mCi was added to 25 μg IgG in 100 μL phosphate-buffered saline (PBS) and the iodination initiated by addition of 10 μL of chloramine T adjusted to 500 μg/mL in PBS. After 45 seconds the reaction was stopped by addition of 10 μL of sodium metabisulfite at 500 μg/mL in PBS Unreacted iodine was eliminated by chromatography of the reaction mixture on a prepacked Sephadex G-25 PD-10 column (Pharmacia) To control the capacity of antibody I/11 to recognize receptor-bound alpha 2 IFN, cells were preincubated for 90 minutes at 4 °C with unlabeled alpha 2 IFN at a saturating concentration of 10,000 U/mL prior to incubation with mouse monoclonal antibodies I/11 and I/O, respectively All incubations were carried out as for the direct binding assay in U-bottomed microtiter plates at a cell density of 10^7 cells/mL in a volume of 200 μL/well. The labeled rabbit antibody was adjusted to approximately 200,000 cpm/well.

IFN assay. Interferon activity was assayed by inhibition of the cytopathic effect of vesicular stomatitis virus (VSV) on bovine MDBK cells (Flow Laboratories,Bethesda, Md) Briefly, confluent monolayer cultures of MDBK cells were incubated for 24 hours at 37 °C with interferon samples of twofold dilution series. Subsequently the cell monolayers were challenged with .1 $TCID_{50}$/100 μL VSV. Inhibition of cytopathic effect was determined after 24 hours' incubation with the challenge virus. Human recombinant DNA alpha 2 IFN served as a reference with a specific activity of 2×10^8 U/mg protein. Titers were standardized to the NIH human leukocyte interferon No. GA 902-530 and are expressed in international units (U/mL).

RESULTS

High-affinity binding of ^{125}I-labeled alpha 2 IFN to specific cell surface receptors of hairy cells was measured immediately before and at various intervals after onset of recombinant alpha IFN therapy. The proportion of hairy cells in peripheral blood is listed in Table 1 for each determination of receptor number. Figure 1 shows the evolution of the number of high-affinity alpha 2 IFN receptors in the first 4 weeks of IFN therapy. Initial numbers of high-affinity alpha 2 IFN receptor sites per cell ranged from 150 to 1,100 in a cell population with more than 90% hairy cells (Table 1). All patients exhibited a 70% to 80% decrease in the number of sites per cell as short as 6 to 12 hours after the first recombinant alpha IFN injection. Twenty-four hours after the first injection, the binding capacity was restored partially in most patients, while it remained at less than 20% of the pretreatment level in two cases (Fig 1). This recovery was only temporary, since binding experiments performed at weekly intervals after onset of therapy revealed a binding capacity consistently below 25% of the pretreatment level. After the second week of treatment, the binding capacity remained virtually unchanged before and six hours after recombinant alpha IFN injections. A decreased binding capacity was also observed in patient 2, who did not respond clinically to IFN therapy. Serum IFN was assayed at each point of determination of binding capacity. While no IFN activity was detectable before onset of therapy, recombinant alpha IFN treatment yielded serum levels between 0 and 40 U/mL. Titers did not correlate significantly with the decreased binding capacity (data not shown).

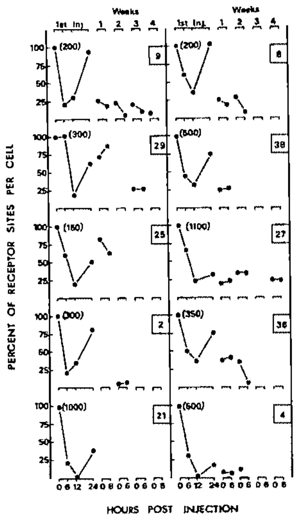

Fig 1. Time course of alpha receptor IFN receptor expression during recombinant alpha 2 IFN treatment of HCL. The results obtained with ten donors are represented individually with time of measurement on the abscissa (weeks after onset of IFN therapy, hours before and after IFN injection) and numbers of specific high-affinity binding sites per cell on the ordinate. These were extrapolated from Scatchard analysis of saturation curves as indicated in Materials and Methods. Saturation curves were based on triplicate values with standard deviations usually less than 10%. The number of receptors per cell before therapy is indicated in parentheses and represents 100% binding capacity. Patient number is indicated in the square at the top right of each graph.

In contrast to the number of binding sites, binding constants (Kd) determined before IFN treatment did not differ significantly and ranged from 1.4 to 6.7 × 10^{-10} mol/L. As exemplified for one case in Fig 2, the affinity of the residual binding sites remained unchanged after IFN injection as compared to the binding properties before treatment.

To distinguish between blocking of receptors by circulating recombinant alpha 2 IFN and decreased expression of high-affinity receptors, the degree of receptor occupation before and six hours after IFN injection was studied in an indirect binding assay with a monoclonal antibody (I/11) directed against alpha 2 IFN bound to its receptor[19] or a control antibody (I/0). Binding of these antibodies was revealed by use of an ^{125}I-labeled rabbit antimouse IgG antibody. As shown in Fig 3, virtually the same amount of radioactivity was bound to hairy cells immediately before and six hours after the first alpha 2 IFN injection with both specific and control antibody. These results suggest that the decreased binding capacity after IFN injection as revealed in the direct binding assay (Fig 1) was not due to occupied receptors. As a control, the IFN binding capacity before and six hours after IFN injection was also determined in the indirect assay. For this purpose the cells were preincubated with a saturating amount of alpha 2 IFN (10,000 U/mL) prior to incubation with the monoclonal antibodies I/11 or I/0, respectively. The results (Fig 3) are consistent with those obtained in direct binding experiments depicted in Fig 1. Thus six hours after the first injection, the IFN binding capacity of hairy cells from patients 4 and 25 was decreased to the same extent in both assays (Fig 3A and B), while the binding capacity of cells from patient 29 remained unchanged before and six hours after the first IFN injection (Fig 3C). As exemplified with patient 2, the IFN binding capacity of peripheral hairy cells remained low, and no bound IFN was detectable after 10 weeks of IFN therapy

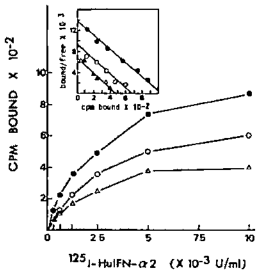

Fig 2. Specific saturable binding of ^{125}I-labeled alpha 2 IFN to hairy cells from patient 38 before (●), 6 hours after (△), and 24 hours after (○) the first IFN injection. The cells were incubated for ninety minutes at 4 °C with various concentrations of ^{125}I-labeled alpha 2 IFN. Nonspecific binding was determined by simultaneous addition to labeled IFN of 2 × 10^5 U/mL unlabelled alpha 2 IFN. Each point represents the mean value of triplicates. Standard deviations were less than 10%. The insert represents the Scatchard plots of the specific saturation curves: The apparent affinity constant as extrapolated from the slope of the curves was approximately 2 × 10^{-10} mol/L. The number of receptor sites per cell was calculated from the extrapolated total number of bound counts per minute on the abscissa.

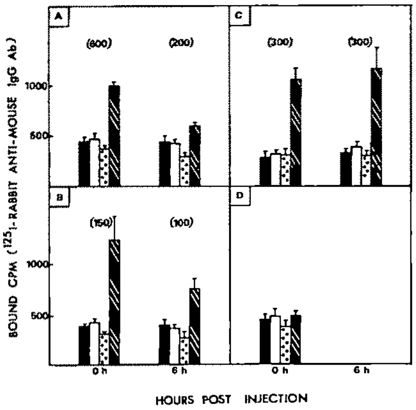

Fig 3. **Indirect detection of alpha 2 IFN bound to cell surface receptors on hairy cells from alpha 2 IFN–treated patients. Peripheral hairy cells were isolated immediately before and six hours after the first alpha 2 IFN injection from patients 4 (A), 25 (B), and 29 (C) and after the tenth week of therapy for patient 2 (D). Specifically, bound alpha 2 IFN was detected by addition of mouse monoclonal antibody I/11 capable of recognizing receptor-bound alpha 2 IFN, as compared to binding of a nonspecific antibody I/0. Binding of these antibodies was revealed by addition of a ^{125}I-labeled rabbit antimouse IgG antibody. To control IFN binding capacity, cells were preincubated with a saturating amount of alpha 2 IFN prior to incubation with monoclonal antibodies I/11 or I/0, respectively. The number of high-affinity alpha 2 IFN receptor sites per cell determined from direct binding-assay is indicated in parentheses and was not detectable in the case of patient 2 (D). ■, cells incubated with control antibody I/0; □, cells preincubated with 10,000 U/mL alpha 2 IFN before incubation with antibody I/0; □, cells incubated with antibody I/11 capable of recognizing alpha 2 IFN bound to its receptor; ▧, cells preincubated with 10,000 U/mL alpha 2 IFN before incubation with antibody I/11.**

(Fig 3D). Consistent results were obtained in the other cases (data not shown). These results suggest that the decreased binding capacity observed in all patients was due to decreased receptor expression rather than to receptor occupation by circulating recombinant alpha IFN.

DISCUSSION

The efficacy of IFN therapy for tumors has been widely investigated over the past few years.[21,22] Due to the poor understanding of mechanisms involved in IFN-mediated tumor regression,[2] predictive parameters for responsiveness of tumor cells to IFN have not been defined as yet. Though presence of IFN receptors appears indispensable for direct IFN action, tumor regression might be mediated by the host, as suggested by the in vivo suspectibility of mouse L1210R cells,[23] which are resistant to the direct effects of alpha and beta IFN in vitro and lack specific receptors.[24] Resistance to IFN can be associated with altered receptor expression and a lower binding affinity[25]; however, resistance to IFN was also observed despite apparently normal receptor expression and also normal induction of response markers such as (2′-5′-)oligo(A) polymerase.[26,27] Further functional characterization of mechanisms activated upon IFN-receptor interaction and particularly of proteins induced in response to IFN[8] will help to elucidate the various forms of IFN resistance and to define markers required for expression of a sensitive phenotype.

The present study was carried out to investigate the initial steps of direct IFN action of hairy cells, which are responsive to alpha IFN treatment in vivo.[17] High-affinity cell surface receptors with binding properties identical to those described for normal peripheral lymphoid cells[13] were found on circulating hairy cells of all ten patients included in the present study. Although pretreatment numbers of detectable binding sites showed up to sevenfold variations (Fig 1), they were of the same order of magnitude as on normal peripheral lymphocytes.[16] After onset of recombinant alpha IFN treatment (see treatment protocol in Materials and Methods), all patients showed a marked decrease of detectable alpha IFN receptors on circulating tumor cells (Fig 1). To distinguish between specific blocking and a decreased number of receptors, bound alpha 2 IFN was revealed indirectly by use of a monoclonal antibody against alpha 2 IFN, which recognizes an epitope still accessible upon receptor binding. Tumor cells from different patients were investigated using this approach immediately before and six hours after the first recombinant alpha IFN injection, as well as upon prolonged IFN therapy (Fig 3). Clearly, the results indicate that the loss of binding sites as early as six hours after onset of therapy was not due to receptor occupation but rather to a decreased receptor expression, called "down-regulation." Alternatively, a pronounced drop in binding affinity may have also accounted for decreased binding of labeled alpha 2 IFN and could not have been distinguished from decreased receptor expression. As shown in Fig 2, the binding affinity of the residual binding sites was unchanged as compared to the data before IFN therapy. Prolonged IFN treatment of cells in vitro may lead to selection of resistant cells.[28] Since a decreased IFN binding capacity was observed rapidly after onset of IFN treatment, selection of tumor cells lacking IFN receptors seems unlikely.

Binding-induced down-regulation of receptor expression was observed in all patients over the entire period of IFN therapy, resulting in marked tumor regression in 9 of 10 patients. Although in most patients receptor expression recovered to a variable proportion within 24 to 48 hours after the first recombinant alpha IFN injection, a permanent "down-regulated" state was established at the latest after the second week of IFN treatment (Fig 1). Down-regulation of alpha IFN receptors, therefore, seems to reflect a continuous response to IFN at the receptor level, indicating that cells remain responsive to IFN despite a low degree of high-affinity receptor expression. After 3 to 4 weeks of treatment, the number of hairy cells in peripheral blood was markedly decreased in most patients (see part 1). However, decreased expression of high-affinity receptors was observed independently of the percentage of tumor cells in the mononuclear cell-enriched fraction (Fig 1, Table 1), suggesting that receptor down-regulation can occur in the majority of circulating leukocytes. Since in most cases the proportion of hairy cells did not vary significantly within the first 2 weeks of treatment (Table 1), receptor down-regulation can hardly be attributed to shifts in cell populations.

Down-regulation might reflect a shift in the dynamic equilibrium between receptor expression and receptor processing.[29] The fraction of occupied receptors at a given concentration of free ligand depends proportionally on the number of expressed receptors.[18] Therefore, receptor down-regulation could result in a decreased sensitivity of the target cell. However, a maximum biological response might require occupation of only a small fraction of accessible receptors, the majority of expressed receptors being "spare."[5] Down-regulation of insulin receptors seems to correlate with insulin resistance in some forms of type II diabetes,[30,31] but it is not clear whether this mechanism could be more generally responsible for decreasing target cell sensitivity for polypeptide ligands. Recently, human Daudi cells rendered resistant to human alpha IFN by prolonged incubation with IFN[27] were shown to "down-regulate" their receptors in the same way as sensitive Daudi cells.[25]

Preliminary results seem to indicate that expression of gamma IFN receptors in hairy cells remains unaffected by alpha IFN treatment (data not shown), in agreement with previous results.[32] Down-regulation occurs rapidly at interferon doses that yield barely detectable serum levels. Thus down-regulation of alpha/beta IFN receptors in vivo could provide a sensitive early response marker, not only for monitoring alpha IFN administration but also to reveal endogenous IFN production in untreated patients with the possibility of distinguishing between alpha and beta IFNs *v* gamma IFN in situations of low or undetectable serum IFN.

Degree and time course of alpha IFN receptor down-regulation were similar in all patients, independent of clinical response to the treatment. The results presented here seem to indicate, therefore, that neither initial IFN receptor levels nor down-regulation is of predictive importance in IFN therapy of HCL. Still, to evaluate the role of receptor down-regulation and its relevance as a response marker for IFN therapy in vivo, it seems important to reevaluate this parameter after prolonged IFN therapy and to extend similar studies to additional cases of IFN-resistant HCL and also to IFN trials in other leukemic diseases.

CONCISE REPORT

Pathways for the Reduction of Oxidized Glutathione in the *Plasmodium falciparum*-Infected Erythrocyte: Can Parasite Enzymes Replace Host Red Cell Glucose-6-Phosphate Dehydrogenase?

By Eugene F. Roth, Jr., Seymour Schulman, Jerome Vanderberg, and Julie Olson

Plasmodium falciparum-infected human red cells possess at least two pathways for the generation of reduced nicotinamide adenine dinucleotide phosphate (NADPH): (1) the glucose-6-phosphate dehydrogenase (G6PD) pathway and (2) the glutamate dehydrogenase (GD) pathway using glutamate as a substrate. Uninfected erythrocytes lack the GD pathway. The NADPH generated can be used to reduce oxidized glutathione (GSSG), which accumulates in the presence of an oxidative stress. In red cell G6PD deficiency, this pathway is reduced or absent, and the host cells as well as the parasites within them are vulnerable to oxidant stress. In view of the presence of the GD pathway in parasitized red cells and the recent description of a parasite-derived G6PD enzyme, we have asked whether the pathways for the reduction of GSSG provided by the parasite can substitute for the host G6PD in red cells deficient in G6PD activity. We have devised a functional assay in which the reduction rate of GSSG is monitored in the presence of buffered infected or control red cell lysates and substrates. Infected G6PD-deficient erythrocytes were obtained from in vitro cultures after a single prior growth cycle of the parasites in G6PD deficient cells to eliminate contaminating normal red cells. The results show that only parasitized red cells can reduce GSSG via the GD pathway. In parasitized G6PD Mediterranean red cells (completely G6PD-deficient), there is a detectable GSSG reduction via the G6PD pathway, not found in uninfected lysates from the same individual. In G6PD A$^-$ (African type, featuring partial deficiency), a small increment in the G6PD-dependent reduction of GSSG can also be detected. However, when compared to G6PD normal red cells, the activities from the parasite-derived pathways are small and could not be considered substitutes for normal host enzyme activity. It is concluded that while the plasmodium provides additional pathways for the generation of NADPH that may serve its own metabolic needs, the host red cells and hence the parasite itself remain vulnerable to oxidant stress.

© 1986 by Grune & Stratton, Inc.

OXIDANT STRESS is often invoked as a mechanism for the inhibition of malaria parasite growth in vivo.[1,2] This mechanism is also used frequently to explain the selective advantage of red cell glucose-6-phosphate dehydrogenase (G6PD) deficiency in malarious parts of the world, particularly wherever *Plasmodium falciparum* is prevalent. In G6PD deficiency, the erythrocyte cannot generate enough NADPH to maintain glutathione in the reduced form when challenged by an oxident stress. Glutathione reductase (GR), the enzyme responsible for the reduction of oxidized glutathione (GSSG), has an absolute requirement for NADPH. The depletion of reduced glutathione (GSH), a protective substance that is also a cofactor in some enzymatic processes, may result in cell injury and parasite death. Previously, it had been demonstrated that malaria-infected red cells contain at least one additional pathway, glutamate dehydrogenase (GD), for the generation of NADPH that could be used to drive the reduction of GSSG,[3] and recently, Usanga and Luzzatto have described an inducible parasite form of G6PD in cultures of *P falciparum* adapted to growth in G6PD-deficient red cells.[4] This enzyme, of course, could also serve to produce NADPH for the reduction of GSSG. The presence of a parasite G6PD enzyme had also been suggested earlier.[5] The two pathways for the reduction of GSSG may be summarized as follows:

(1) G6PD pathway:

$$\text{Glucose-6-phosphate} + \text{NADP}^+ \xrightarrow{\text{G6PD}} \text{6-phosphogluconate} + \text{NADPH}$$

$$\text{GSSG} + \text{NADPH} \xrightarrow{\text{GR}} 2\text{GSH} + \text{NADP}^+$$

(2) GD pathway:

$$\text{Glutamate} + \text{NADP}^+ \xrightarrow{\text{GD}} \alpha\text{-ketoglutarate} + \text{NH}_3 + \text{NADPH}$$

$$\text{GSSG} + \text{NADPH} \xrightarrow{\text{GR}} 2\text{GSH} + \text{NADP}^+$$

where NADP$^+$ is oxidized nicotinamide adenine dinucleotide phosphate.

We have asked whether the alternate parasite-derived pathways for GSSG reduction could substitute for the normal erythrocyte G6PD activity. To answer this question, we have devised a functional assay for the reduction of GSSG using infected red cell lysates, substrates, and cofactors for each of the pathways. Although these methods do not allow calculation of classical kinetic parameters of enzyme function, they permit estimation of the relative quantitative importance of each pathway. In addition, they serve as a

confirmatory method for the more direct enzyme assays, which are technically difficult when only minute traces of enzymes are present.

MATERIALS AND METHODS

The assay system for the estimation of GSSG reduction rates consisted of 100 mmol/L Tris buffer, pH 7.5 or 7.0 as indicated, with 1 mmol/L EDTA to which was added NADP$^+$, GSSG, and either monopotassium glutamate or glucose-6-phosphate (monosodium salt) (G6P), all at a final concentration of 400 μmol/L. This pH range was chosen because it spans the conditions likely to be found in intact red cells. Since no significant differences were found at these pH extremes, only results for pH 7.5 are reported. The mixture was prewarmed in a stoppered 10-mL Erlenmeyer flask at 37 °C on a shaking water bath, and aliquots (10 to 100 μL) of the freeze-thawed red cell lysate and distilled water were added to bring the final volume to 1.0 mL. Incubation was continued usually for 15 minutes (but up to 120 minutes if needed), and the reaction was stopped by addition of an equal volume of cold meta-phosphoric acid-EDTA-NaCl solution used for the extraction of GSH according to the method of Beutler.[6] The reduction of GSSG was linear for the incubation times used, and the loss of the GSH produced was less than 1%. The supernatants were clarified by centrifugation and then assayed for GSH by the colorimetric method of Beutler,[6] modified to accommodate small volumes. For each hemolysate and for each substrate, two blanks were incubated to account for any nonspecific reduction of GSSG and to detect residual background GSH in the hemolysates. One blank lacked substrate (glutamate or G6P), and another lacked GSSG and NADP$^+$. In general, blanks displayed absorbances at the appropriate wavelength (412 nm), which were not more than 3% of the complete system with enzymes, substrates, and cofactors. When no detectable GSSG-reducing activity was observed, subtraction of the blank values did not result in "negative values" In some experiments, exogenous glutathione reductase was added to ensure that this enzyme would not be the limiting factor in the reaction cascade. Accordingly, Baker's yeast GR type III (Sigma Co, St Louis) was obtained as an ammonium sulfate suspension and dialyzed against the Tris-EDTA buffer to which 10 μmol of flavine adenine dinucleotide (FAD) was added as a stabilizer. In some experiments, .88 Sigma units of GR (Sigma Chemical, St Louis) was added to the incubation flask, but the addition of this enzyme generally did not affect the rate of GSSG reduction (one Sigma unit is defined as the reduction of 1.0 μmol coenzyme A–glutathione mixed disulfide/min at pH 5.5 at 25 °C) Removal of the ammonium sulfate by dialysis was necessary because NH$_4^+$ and/or NH$_3$ was inhibitory for GD.

Plasmodium falciparum (FCR–3 strain) was cultured in normal and G6PD-deficient red cells as described by Jensen and Trager[7] and enriched for later parasitic stages (trophozoites and schizonts) by sedimentation with gelatin.[8] Plasmodium cultures were not adapted to growth in G6PD-deficient cells for a number of cycles before harvesting the cells for the assay. However, to avoid contaminating G6PD-deficient red cells with significant numbers of normal erythrocytes, parasites at high parasitemias (obtained by gelatin sedimentation) were added to G6PD-deficient cells for a single growth cycle. When these parasites had attained the later stage of trophozoite/schizonts, another gelatin sedimentation was performed, and the parasite-rich layer was added to a fresh aliquot of G6PD-deficient cells. The biochemical studies were performed after gelatin sedimentation of this second aliquot of cells (at the end of a total of two growth cycles). Thus admixed normal red cells were not harvested for the biochemical studies. The cells were washed three times in the Tris-EDTA buffer used for the assay and counted on a Model Z Coulter Counter. After the addition of NADP$^+$ (1 mmol/L) and FAD (10μmol/L) to stabilize G6PD and GR, respectively, the packed cells were lysed by two freeze-thaw cycles.

Hemoglobin (Hb) content of the lysates was determined by the cyanmethemoglobin method. Blood was obtained from known G6PD-deficient donors used for previous studies.[9,10] Both G6PD Mediterranean and G6PD A$^-$ types were used in this study, and a spectrophotometric kinetic assay method to measure G6PD activity was used as described previously.[9,10] The red cells with G6PD Mediterranean displayed no spectrophotometrically detectable enzyme activity, whereas the G6PD A$^-$ red cells contained 1.1 U/g Hb of enzyme activity (norman range, 8.98 ± 77 SD). The sensitivity limits of the GD pathway were tested by incubating purified GD from bovine liver (type III, Sigma Corp, St Louis) with appropriate substrates, including the dialyzed yeast GR.

The sensitivity limits for G6PD were tested by diluting a normal red cell lysate of known G6PD activity and incubating it with appropriate substrates as described. In this method, as little as one thousandth of the normal red cell G6PD activity could be detected, and as little as 50 Sigma microunits of bovine liver GD/mL could be measured via reduction of GSSG. (One sigma unit of GD is defined as the reduction of 1.0 mmol α-ketoglutarate to L-glutamate/min at pH 7.3 at 25 °C). Results for the lysates were expressed as μmol GSH generated/g Hb/h. This method of expressing GSSG reduction rates was adopted because preliminary experiments indicated that although there is a change in MCH (mean corpuscular hemoglobin) during parasite growth, the cyanmethemoglobin method is not sensitive to the decline in hemoglobin concentration. This phenomenon (which will be the subject of a separate report) occurs because that portion of the hemoglobin converted to the malarial pigment hemozoin has considerable absorbance at the same wavelength as that used for the measurement of cyanmethemoglobin Since Drabkin's reagent measures the concentration of cyanmethemoglobin and hemozoin together, only very minor changes are seen in the infected red cell. Thus, for the purpose of a constant denominator in enzyme measurements, the cyanmethemoglobin method is valid All spectrophotometric measurements were made on a Gilford model 240 UV-visible recording spectrophotometer

To test the role of young red cells in the reduction of GSSG, red cells from normals and a G6PD-deficient Mediterranean donor were separated by density according to the method of Vettore et al[11] on Percoll-Renografin gradients. Three layers were defined—top, middle, and bottom—and these were lysed and studied for GSSG-reducing activity in the presence of glucose-6-phosphate and NADP$^+$.

RESULTS

Lysates from infected erythrocytes of all genotypes possessed a measurable capability to reduce GSSG in the presence of glutamate by means of the enzyme glutamate dehydrogenase. No glutamate-dependent activity was found in the uninfected control cells (Table 1). This finding demonstrates that the parasites were disrupted by the freeze-thaw cycles and that release of intracellular material had occurred. The presence of this enzyme in a number of plasmodia including *falciparum* has been described previously.[3,12]

As expected from spectrophotometric data on red cell G6PD enzyme activity, considerable glucose-6-phosphate–dependent reduction of GSSG occurred in the presence of normal red cell lysates, and no GSSG reduction occurred in the presence of lysates from G6PD Mediterranean cells (Table 1). Lysates from G6PD A$^-$ were capable of reducing

Table 1. The Reduction of Oxidized Glutathione by Lysates of *P falciparum*–infected Red Cells Using Glutamate or Glucose-6-phosphate as Substrates

Lysate	Parasitemia (%)	Glutamate (µmol GSH/g Hb/h)	Glucose-6-PO$_4$ (µmol GSH/h/gHb)
Normal infected (3)	38%	25.4 ± 1.3 SD	727.0 ± 35.2 SD
Normal control (2)	—	0.0	785.0
G6PD Mediterranean infected	30%	21.0	28.9
	60%	73.5	82.7
G6PD Mediterranean control (3)	—	0.0	0.0
G6PD A$^-$ infected	38%	38.6	221.0
	72%	71.5	162.0
	51%	48.0	209.0
G6PD A$^-$ control (3)	—	0.0	159.0 ± 11.9 SD

Numbers in parentheses indicate numbers of different blood donors

GSSG in the presence of glucose-6-phosphate at a reduced rate of about 15% to 20% of the normal rate, which is comparable to their relative enzyme activity as measured by direct kinetic assays. Of great interest is the presence of detectable G6PD activity (as detected by reduction of GSSG) in lysates from *infected* G6PD Mediterranean red cells. Since the uninfected cell lysates from the same donor contained no detectable activity, it is concluded that the enzyme responsible for this activity is derived from the parasites.

Red cell age (density) is an important determinant of G6PD-dependent GSSG-reducing activity in normal erythrocytes (Table 2). The reduction rates of the most buoyant cell layer exceeded the rates of the bottom (most dense) layer by 100 to 200 µmol GSH/g Hb/h. However, when top and bottom layers of G6PD-deficient cells were compared in the same assay, a difference of only 8 µmol GSH/g Hb/h was observed (Table 2). This finding suggests that the G6PD-dependent GSSG reduction rates seen in infected G6PD-deficient cells (Table 1) were not related to preferential invasion of young red cells by plasmodia.

These observations are consistent with the data of Usanga and Luzzatto,[4] who detected G6PD activity in *P falciparum* grown in the same kind of G6PD-deficient red cells. There is also a small increment in glucose-6-phosphate–dependent GSSG reduction seen in parasitized G6PD A$^-$ cells, which is consistent with the coexistence of parasite- and host-derived G6PD enzymes (Table 1). It should also be noted that the increments in GSSG reductive capacity attributed to parasite enzymes does not approach levels for G6PD-dependent activity in normal, uninfected cells. For example, if the activity for the reduction of GSSG in the presence of glucose-6-phosphate in the infected G6PD Mediterranean sample with 60% parasitemia is extrapolated to 100% parasitemia, the value amounts to 138 µmol GSH produced/g Hb/h. This value is still in the deficient range, although it now resembles the African type of G6PD deficiency more than the Mediterranean type. Similar calculations for GD activity yield similar small increments in GSSG reductive capacity. Thus, while the parasitized G6PD-deficient red cells clearly have some GSSG reductive capacity, it does not attain levels found in normal erythrocytes.

Table 2. The Effect of Red Cell Age on G6PD-dependent Reduction of Oxidized Glutathione in Uninfected Normal and G6PD-deficient Red Cells

	Reduction of GSSG (µmol GSH/gHb/h, mean ± SD)	
Density Gradient Layer	Normal RBCs	G6PD-deficient RBCs
Top (n = 4)	1134 ± 116	9.7 ± 5.5
Middle (n = 4)	978 ± 129	1.7 ± .6
Bottom (n = 4)	927 ± 92	1.7 ± .5
Whole blood (n = 4)	1086 ± 44	2.0 ± .6

When the same experiments were performed at pH 7.0, there was a slight diminution of activity seen with glutamate and a comparable small increase seen with glucose-6-phosphate (data not shown). Incubation of parasites isolated by saponin lysis of normal infected erythrocytes demonstrated an enrichment of glutamate-dependent GSSG reduction, but there remained a twofold to threefold excess of G6PD-derived activity. This presumably represents mostly contamination with host proteins (data not shown).

DISCUSSION

These data support the observations of Usanga and Luzzatto[4] of a parasite-derived G6PD enzyme. The parasite enzyme is much easier to detect in G6PD Mediterranean red cells, where the background enzyme activity approaches zero by spectrophotometric techniques. The amounts present are still very difficult to detect in crude lysates by spectrophotometric methods, because the presence of hemoglobin limits the concentration at which the lysates can be used. The assay used in this report does not directly depend on spectrophotometry of hemoglobin-containing samples and therefore does not suffer from this limitation. On the other hand, where a great deal of enzyme is present (as in G6PD-normal red cells), it is very difficult to detect a small increment from any parasite-derived G6PD enzyme. Therefore, our failure to detect "supernormal" activity in G6PD-dependent GSSG reduction in infected normal red cells should not be taken to mean that the parasite enzyme is not present in normal infected red cells. Techniques that physically separate the human and parasite enzyme would be better suited for the detection of a parasite G6PD in the presence of the host cell enzyme.

The present data, which were obtained from parasites not fully adapted to growth in G6PD-deficient cells (according to the procedures of Usanga and Luzzatto[4]), demonstrate that parasite G6PD is expressed to some extent and does not require a prolonged period of adaption or selection before becoming detectable. While this finding is not in agreement with the data of Usanga and Luzzatto, this disparity may merely relate to differences in the strains used. Indeed, it may well be that the single growth cycle in G6PD-deficient cells that we used before beginning the experiment may be enough to stimulate parasite enzyme production in the FCR-3 strain. Unfortunately, omission of this preexperiment growth cycle would open the possibility that any G6PD enzyme activity subsequently detected could merely be a contaminant from infected normal red cells. Further experiments that follow GSSG-reducing capacity through many cycles of parasite growth need to be performed before a clear picture of parasite adaptability is obtained.

Although at this time no one can declare what level of G6PD activity is sufficient for the parasite itself, it is clear that G6PD activity of parasitized deficient red cells is still well below that of normal cells. This implies that the parasite, which requires the host red cell for the asexual stage of its proliferation, continues to be vulnerable to oxidative challenge.

CONCISE REPORT

Antibodies to Human T-Lymphotropic Virus Type III (HTLV-III) in Saliva of Acquired Immunodeficiency Syndrome (AIDS) Patients and in Persons at Risk for AIDS

By D.W. Archibald, L. Zon, J.E. Groopman, M.F. McLane, and M. Essex

Whole saliva samples collected from available people at risk in Boston for infection with human T-lymphotropic virus type III (HTLV-III/LAV), from late 1984 through early 1985, were analyzed for the presence of antibodies to viral proteins. Fourteen of 20 (70%) acquired immunodeficiency syndrome (AIDS) patients and 14 of 15 (93%) AIDS-related complex (ARC) patients had salivary antibodies that reacted with the virus-encoded glycoproteins gp160 and gp120 of HTLV-III infected cells. All of the AIDS and ARC patients had serum antibodies to the same antigens. Of 20 sex partners of AIDS/ARC patients, nine (45%) showed anti-HTLV-III antibodies, and four of 18 (22%) healthy homosexual males also were positive for such antibodies. Serum and salivary antibody status were the same in these groups. A minority of those patients positive for salivary antibodies to *env* gene-encoded gp160 and gp120 also had salivary antibodies to *gag* gene-encoded proteins of 55,000, 24,000, and/or 17,000 daltons. Immunoglobulin A (IgA) class antibodies comprised the majority of the salivary antibody response. The spectrum of HTLV-III proteins detected by the salivary and serum antibodies was similar. The possibility that secretory IgA from the gut-associated lymphoid system may play a role to restrict salivary transmission of HTLV-III should be considered.

© 1986 by Grune & Stratton, Inc.

IN THE UNITED STATES and Europe, the acquired immunodeficiency syndrome (AIDS) occurs primarily in sexually active homosexual men, intravenous drug users, and blood product recipients.[1,2] Heterosexual partners of all of the above have developed AIDS.[3] The apparent routes of transmission of the human T-lymphotropic viruses (HTLV) include close sexual contact, transfusion of blood products, and parenteral exposure. One member of the HTLV family of retroviruses, HTLV-III/LAV, is generally accepted to be the etiologic agent of AIDS.[4-7] This virus has been isolated from a high percentage of patients with AIDS or AIDS-related complex (ARC),[5] and antibodies to it have been found in 88% to 100% of AIDS patients and high-risk individuals.[8,9]

Another horizontally transmissable retrovirus, feline leukemia virus (FeLV) is responsible for a series of lymphoproliferative and cytopathic diseases similar to those of the HTLV family. FeLV has been shown to be transmissable via saliva,[10] and it replicates well in the salivary gland acinar cells.[11] Moreover, saliva contains the highest level of infectious particles of any body fluid and is easily passed by mutual grooming in communally housed cats. Oronasal lymphoid cells are the first cells to show evidence of FeLV infection following an oral inoculation[11]; thus, the upper respiratory tract can also be the portal of viral entry as well as the site of transmission.

HTLV-III infectious particles have recently been isolated from the saliva of four of ten ARC patients and four of six healthy homosexuals, and retroviral particles were observed by electron microscopy in the saliva in one of four AIDS patients tested.[12] These patients were all seropositive for antibodies to HTLV-III.[12] Saliva passed via kissing has also been implicated as a vehicle of transmission in at least one case of HTLV-III infection.[13]

In respiratory viral diseases, the presence of immunoglobulin A (IgA) antibodies, which are found in higher concentrations in mucosal secretions, ie, saliva, correlates better with viral immunity than does the level of antiviral serum antibodies.[14] We report here that antibodies directed to HTLV-III proteins were found in the whole saliva of patients with AIDS and ARC.

MATERIALS AND METHODS

Whole saliva was collected from patients and healthy participants in Boston, during late 1984 and early 1985, and stored at −70 °C before being analyzed under code. Following 1:2 dilution with phosphate buffered saline or water, samples were centrifuged and passed through 0.22 μm pore size filters (Millipore Corp, Bedford, Mass). Radioimmunoprecipitation of ^{35}S-cysteine–labeled H9/HTLV-III–infected and H9-uninfected cell lysates was performed as previously described[15] except that Protein-A beads were first reacted with 10 μL of sheep anti-human secretory IgA serum (Cappel Laboratories, Inc, Cochranville, Pa) before addition of 150 μL of the saliva samples. Serum from an AIDS patient known to be positive for HTLV-III antigens p24, p55, gp120, and gp160 was used as a positive control. Immunoprecipitates were analyzed in a 10% acrylamide resolving gel with a 3.5% stacking gel, according to the discontinuous buffer systems of Laemmli[16] Autoradiography was carried out for five days at −70 °C. Serum samples from the same patients were obtained at approximately the same time and were tested by immunoprecipitation as described earlier.[15]

RESULTS

The positive saliva samples reacted with proteins of molecular weights 160,000 and 120,000 that were present in the

infected cell lysate and not in the uninfected cell lysates. These correspond to *env* gene glycoproteins from HTLV-III as previously reported.[9,17] Salivary antibodies usually did not recognize *gag* viral proteins p55 and p24 that were precipitated by serum from an AIDS patient with known high anti–HTLV-III titers as shown in Fig 1. However, proteins of molecular weight 55,000, 38,000, 27,000, 24,000, and 17,000 were occasionally precipitated by some saliva samples that also contained antibodies to gp160 and gp120. Of 20 AIDS patients, 14 had salivary antibodies, while 14 of 15 ARC patients had salivary antibodies to gp160 and gp120. Nine of 20 healthy sex partners of AIDS and ARC patients were also salivary antibody positive. Two of these partners of AIDS patients had virus isolated from their plasma, but had no serum antibodies and also had no evidence of antibodies in their saliva.[13] Four of 18 healthy homosexual males were positive for salivary antibodies. As additional controls, ten patients hospitalized for cancer therapy, including five leukemia/lymphoma patients and five carcinoma patients, were also negative. Eleven laboratory workers with exposure to HTLV-III products were similarly negative for salivary antibodies to HTLV-III. A serum antibody positive transfusion healthy patient also had salivary antibodies to HTLV-III proteins, indicating that the gut-associated lymphoid system can be stimulated by systemic HTLV-III infection or that viral replication could occur there.

The presence of salivary antibody to HTLV-III correlated with the serum antibody status except that not all serum antibody positive AIDS patients had salivary antibody. The class of antibody in the saliva that reacted with the virus antigens was IgA, since failure to use an anti-IgA antibody to bind the salivary immunoglobulin led to a greatly diminished reactivity. The data is summarized in Table 1

DISCUSSION

Mucosal IgA is known to be protective against some viral diseases, presumably by blocking viral attachment to and/or entry into cells. FeLV is an exogenous transmissable retrovirus, as is HTLV-III, that can be passed orally via saliva even though the virus cannot survive the pH of the stomach. Therefore, the FeLV retrovirus must be able to enter the mucosal cells of the oropharyngeal region. Mucosal antibodies found in secretions such as saliva would be expected to be at least partially protective against this process. Since infectious HTLV-III has been found in saliva, the possibility exists that mucosal IgA antibodies may play a protective role against virus transmission either by preventing oropharyngeal viral entry or by blocking virus and preventing viral spread via saliva. The envelope directed IgA antibodies found in saliva would be excellent candidates for the blocking action. The oral polio vaccine protects not only by initiating systemic antibodies, but also by stimulation of IgA-producing lymphocytes in the alimentary tract. Reinfection of the gut is greatly reduced by the local IgA immunity.[18] Similar-

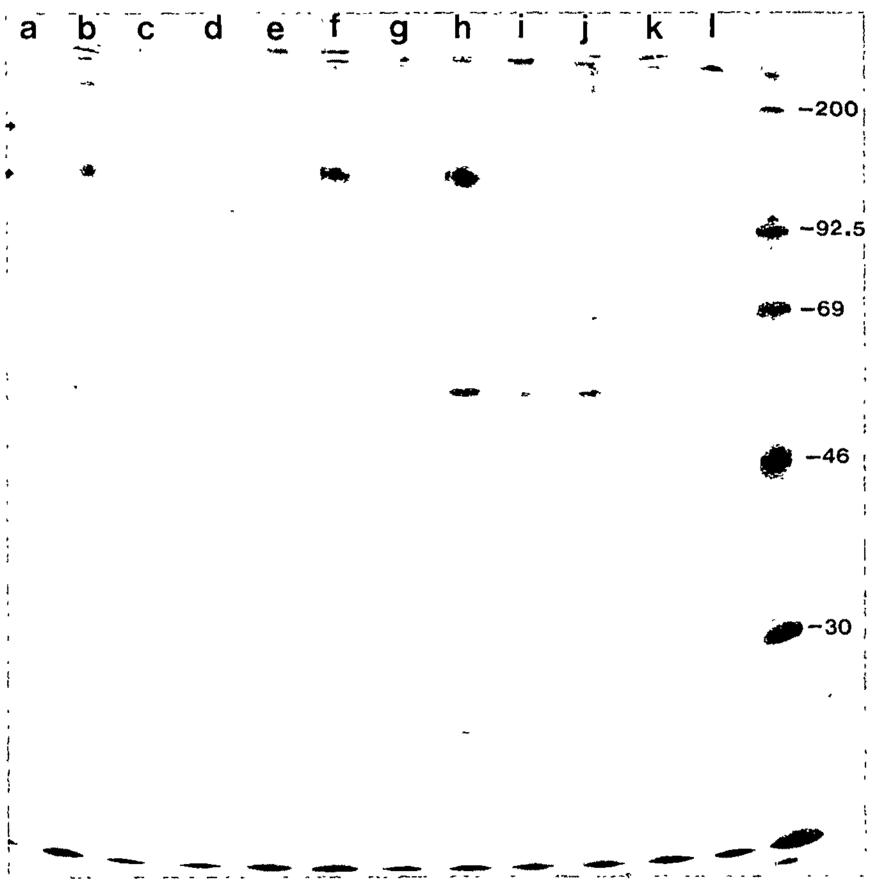

Fig 1. Soluble cell lysates were prepared from H9 (lanes a, c, e, g, i, and k) and H9/HTLV-III (lanes b, d, f, h, j, and l) cells exposed to ^{35}S-cysteine, harvested, and lysed with radioimmunoprecipitation assay (RIPA) buffer. These lysates were then reacted with 150 μL of a 1:2 dilution of saliva which had been bound to Protein A-Sepharose CL-4B (Protein A-beads, Sigma, St Louis) with 10 μL of sheep anti-human IgA sera. Samples were as follows: saliva from AIDS patient No 1 (lanes a and b); normal laboratory worker (lanes c and d); AIDS patient No. 2 (lanes e and f); AIDS patient No. 3 (lanes i and j); AIDS patient No. 4 (lanes k and l); reference serum from AIDS patient known to be positive for HTLV-III antigens (lanes g and h). Approximate molecular weights in thousands are at the right.

*Sera from two laboratory workers, one healthy homosexual, and all cancer patients were unavailable for testing

ly, mucosal IgA in vaginal fluid, semen, saliva, gut secretions, and tears could be evaluated for its ability to alter HTLV-III infection.

The fact that only 70% of AIDS patients had detectable salivary antibody may be related to the low antibody titers usually found in saliva which could be reduced even more as a result of the immunodeficient state in AIDS. The demonstration of salivary antibodies in all other persons who were serum antibody positive indicates that the gut response is closely linked to the systemic humoral response. Further, it may also be related to salivary viral levels. Infectious virus in saliva has been shown to be more easily isolated from healthy homosexuals and ARC patients than from AIDS patients.[12] Thus, salivary antibody levels may drop as salivary viral levels drop. Assuming a normal concentration of 20 mg/100 mL[19] of IgA in whole saliva as compared with 328 mg/100 mL of IgA and 1,230 mg/100 mL IgG in serum, then there is only 1/80th as much potential antibody in saliva as compared with total serum levels. Salivary IgG levels are usually negligible even when transudation of serum from around the teeth is included.

Gp160 and gp120 are the likely targets of virus neutralizing antibodies. The finding of IgA antibodies directed toward HTLV-III *env* proteins in saliva also provides an opportunity for studies of IgA in other body fluids, such as semen, vaginal fluids, and tears. The role of these antibodies, in the various secretory fluids, may play in viral transmission has not been evaluated. If salivary IgA antibodies are found to be neutralizing, then questions concerning the strain specificity of antibodies directed toward HTLV-III proteins should be addressed for all mucosal fluids.

Salivary IgA antibodies were detectable in all the subjects (27 of 27) that were positive for serum antibodies except the AIDS patients. This raises the possibility that a screening test for the detection of virus-infected healthy carriers might be conducted using saliva rather than blood.

CONCISE REPORT

Immunoglobulin Gene Rearrangements in Remission Bone Marrow Specimens From Patients With Acute Lymphoblastic Leukemia

By Barbara A. Zehnbauer, Drew M. Pardoll, Philip J. Burke, Michael L. Graham, and Bert Vogelstein

Recombinant DNA probes for the joining (J_H) segment of the immunoglobulin heavy chain gene were used to detect molecular rearrangements of this gene in the DNA of bone marrow cells obtained during remission of acute lymphoblastic leukemia (ALL). This molecular approach was optimized and found to exceed the sensitivity of conventional morphologic screening for detecting residual leukemia cells; one leukemic cell in 500 normal nucleated bone marrow cells was easily detected using this approach. In the present study, bone marrow from three of seven patients in complete clinical remission (defined morphologically) contained leukemic cells in these proportions. This analysis may be of use in evaluating the status of clinical remission in selected ALL patients.

© 1986 by Grune & Stratton, Inc.

THE STAGES of leukemia are usually assessed by morphologic examination of cells from the peripheral circulation and/or bone marrow of patients. In general, bone marrow aspirates containing less than 5% blast cells and recovering normal elements indicate a remission stage. However, this level of detection is obviously suboptimal since patients showing less than 5% blast cells could still have millions of leukemic cells in their bone marrow. The presence of an increased normal blast population due to the effects of receiving drug treatment can artificially raise the number of normal blast cells without actual leukemic cell proliferation. Furthermore, in the L_1 and L_2 forms of acute lymphoblastic leukemia (ALL), it is not uncommon to see lymphocytic infiltration in the recovering bone marrow. Whether these cells are of normal or malignant origin is not always clear from morphologic examination.

Among the recent findings in acute lymphocytic leukemia is the rearrangement of immunoglobulin genes in the vast majority of ALL cases either of null or B cell origin.[1] One of the first events leading to expression of immunoglobulin (Ig) genes is the recombination of the distant gene segments, designated variable (V_H), diversity (D), and joining (J_H), of the Ig heavy chain gene.[2]

Intervening DNA segments are deleted during this recombination. The joined segments combine with a constant region heavy chain gene (C_H) and together code for the Ig heavy chain protein.[3] The rearrangement of Ig gene segments has been detected in leukemic cells by examining the changes in electrophoretic mobility of DNA fragments, produced by restriction endonuclease cleavage, which bridge the point at which recombination occurred. Most ALL cells contain a rearranged Ig heavy chain gene,[1] even though the light chain genes are often not rearranged.[4]

The detection of the presence of clonally derived cells with specific Ig gene rearrangements could be useful in evaluating the remission status of ALL patients.[5,6] However, to our knowledge, the utility and logistics of such a study has not been reported. We describe here our initial experience using this strategy in patients in remission. By optimizing several parameters, we noted that remission marrows containing as few as one leukemic cell in 500 normal cells could be readily identified. Furthermore, bone marrows from three of seven patients in complete remission (defined morphologically) contained leukemic cells in proportions allowing their detection by this assay. This analysis could be a useful adjunct to morphologic examination, especially in patients in whom alternative therapies are being considered or in marrows of questionable morphology.

MATERIALS AND METHODS

Cells Bone marrow aspirates were diluted 1:5 with RPMI-1640 and allowed to sediment at 1 g for one hour Cells from the buffy coat and the floating spicules (released by repeated passage of the spicules through a 25G needle) were pooled and washed with RPMI-1640. Mononuclear cells were then purified on Histopaque 1.077 (Sigma, St Louis) step gradients. A minimum of 3×10^6 purified mononuclear cells was required for this analysis of rearranged Ig genes.

Hybridization analysis DNA was purified by sodium dodecyl sulfate (SDS)-proteinase K digestion[7] followed by phenol-chloroform extraction and DNA concentrations were determined by the diphenylamine method.[8] DNA was cleaved consecutively with *Hind*III and *Bam*H1 restriction endonucleases obtained from Bethesda Research Laboratories (Bethesda, Md) using 10 U of enzyme per microgram of DNA in reaction buffers recommended by the supplier. Of the cleaved DNA, 7.5 μg were concentrated by ethanol precipitation and subjected to vertical agarose gel electrophoresis using a slot of 3 × 8 mm. Electrophoresis, transfer to nitrocellulose, and hybridization were performed as previously described[9,10] The *Bam*H1–*Hind*III fragment of the J_H region, cloned in plasmid pBR322, was provided by Dr Philip Leder. Nick translation of this plasmid clone was performed using the kit from Amersham (Arlington Heights, Ill) following the supplier's conditions but using 10 ng of DNA and 50 μCi of α^{32}P-dCTP (3,200 Ci/mmol) per reaction for one hour at 17 °C. Autoradiography was performed for 15 hours at −80 °C using Kodak XAR-5 film (Rochester, NY) and Dupont Lightning Plus intensifying screens (Dupont, Wilmington, Del).

RESULTS

In order to optimize the detection of clonally derived cells containing identically rearranged Ig genes, we concentrated on two aspects of the analysis: methods of bone marrow preparation and nucleic acid hybridization techniques. It was of paramount importance that the bone marrow aspirate be drawn with minimal blood contamination, which could obviously dilute any leukemic cells present in the marrow with a much larger number of normal circulating cells. A two- to fivefold enrichment for mononuclear cells was achieved by techniques described in the Materials and Methods section.

Molecular biological parameters were optimized by implementing a model bone marrow population prepared by in vitro mixing of nonrearranged DNA from normal cells with varying amounts of clonally rearranged DNA from leukemic blast cells. One variable examined was the portion of the J_H region that would produce a strong "signal" upon hybridization to the rearranged DNA fragment and at the same time yield a minimum of "noise" or background hybridization to other nonspecific sequences. In this regard, several subfragments of the J_H region (Fig 1) of the Ig heavy chain gene were tested in hybridization. Fragments A through E, shown in Fig 1, which were produced by cleavage with the enzyme Cpf I (Worthington Diagnostics, Freehold, NJ), and the entire *Bam*H1–*Hind*III fragment, were tested individually as hybridization probes. Fragments A and B did not detect most rearranged genes, fragment C yielded the same background but less signal than the total plasmid clone, and fragments D and E yielded reduced background but also reduced signal Therefore, the 6 kb *Bam*H1–*Hind*III fragment encompassing all the J_H genes was used in further experiments.

Three different radiolabeling techniques of the cloned J_H *Bam*H1–*Hind*III fragment were compared. The conditions were varied to produce a probe with a high specific activity, a low degree of random hybridization or background, and a level of detection sufficient to detect <5% leukemic cells in a normal population. Synthesis of RNA from the J_H probe using the SP6 polymerase system[11] (Promega Biotec, Madison, Wisc) fulfilled the first two criteria but not the third. "Oligo-labeling," performed using random hexamers as primers,[12] as well as nick translation produced probes of high sensitivity, but the background was somewhat less using the nick translated probe. A high specific activity (2.5×10^9 dpm/μg) using nick translation was obtained by using only 10 ng of the J_H plasmid in a reaction mixture containing 50 μCi of α^{32}P-dCTP (3,200 Ci/mmol)

The choice of restriction endonuclease with which the genomic DNA was cleaved was varied to select a combination which would reveal rearrangement of J_H sequences in a DNA fragment with a significantly different mobility from the normal nonrearranged DNA upon electrophoresis. A combination of *Bam*H1 plus *Hind*III produced a 6 kb DNA fragment in a normal sample (nonrearranged DNA) corresponding to the complete J_H probe while rearranged fragments in the leukemic samples were usually of significantly different size. Other enzyme combinations tested did not produce easily distinguishable, rearranged fragments from leukemic cells as frequently as the *Bam*H1–*Hind*III combination. In addition, the *Bam*H1–*Hind*III combination had optimal complementarity with the probe. Fig 2A shows a typical experiment in which rearranged DNA fragments were detected in DNA extracted from leukemic cells of patients during the active phase of their disease (presentation or relapse). In each case, one to three rearranged fragments were identified and usually a normal, 6 kb fragment was also observed, representing unrearranged Ig alleles still remaining in the leukemic cells or nonleukemic cells present in the cell fractions used for analysis.

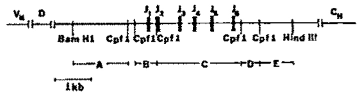

Fig 1. Map of immunoglobulin J_H region of the human genome. CPF-1 sites were mapped in the region described in ref. 3.

Using the optimized methods, mixing experiments were performed to demonstrate the limits of detection of leukemic cells in the assay. One leukemic cell in 333 normal cells could be clearly detected in the original autoradiograph (Fig 2B). The source of the normal cells (placenta or peripheral blood mononuclear cells) did not affect this sensitivity. Since the cell fractionation procedure resulted in a two- to fivefold enrichment of mononuclear cells from bone marrow, one could specifically detect, at minimum, one leukemic cell in 500 normal bone marrow cells.

We next examined actual remission bone marrow samples to determine how frequently leukemic cells could be detected using the recombinant DNA analysis In each case, the bone marrow sample examined had been independently diagnosed as indicating complete clinical remission by morphologic methods. In Fig 3, patient No. 1 is illustrative of the results that can be achieved. This patient was a 25-year-old male who presented with ALL in Feb 1985 (Table 1). Clinical remission was achieved in May 1985 following treatment with prednisone and vincristine and then arabinoside-c (ara-c) with daunomycin given in a timed sequence. At the time of bone marrow recovery, an aspirate of the bone marrow was obtained. Maturation of all cell types was observed with normal numbers of blast cells (<5%) After fractionating the bone marrow to enrich for mononuclear cells, we analyzed the DNA of the cells for rearranged bands characteristic of the patient's leukemic cells. In DNA from his leukemic cells (obtained at the time of initial disease presentation), two rearranged fragments of 3.5 kb and 2.5 kb were detected (Fig 3, lane L, patient No. 1). These same fragments were detected in the DNA from the clinical remission bone marrow (Fig 3, lane R, patient No 1). Note that the relative intensity of the rearranged bands is much less in lane R than in lane L, even though lane R contained 7.5 μg of DNA and lane L contained only 0.5 μg of DNA. We estimated that the rearranged bands in the remission sample corresponded to 1% to 2% leukemic cells in this bone marrow. The prevalent band at 6 kb derives from normal cells in the bone marrow The 4.3 kb fragment was an internal control for the hybridization reaction.

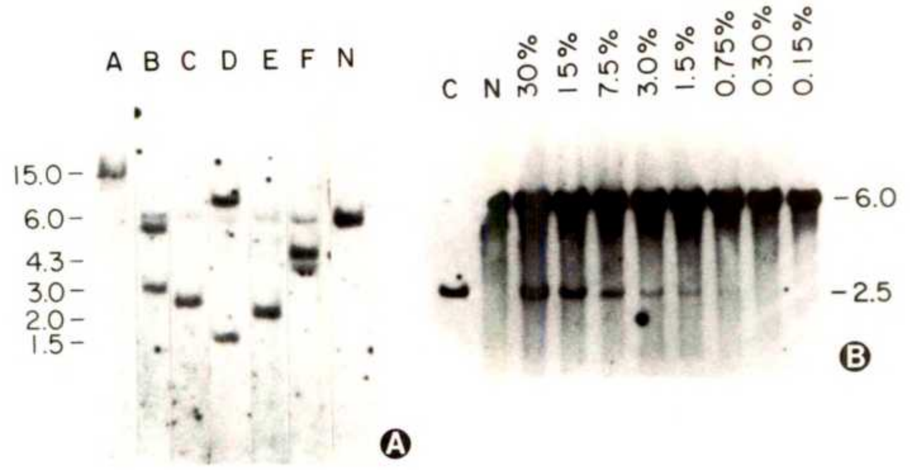

Fig 2. (A) Rearranged J_H fragments in patients with leukemia. DNA was extracted from ALL cells of six patients (A through F) during the active phase of their disease (presentation or relapse). As described in Materials and Methods, 0.5 to 2.0 μg of DNA was cleaved with *Bam*H1 and *Hind*III, and these digests were used in electrophoresis, Southern transfer, and hybridization. An autoradiograph of the Southern blot is shown with sizes of fragments noted on the left in kilobases (kb). Patients A, C, and E had one rearranged allele and one deleted allele, while patients B, D, and F had patterns which indicated a different rearrangement for each of two alleles. (B) Mixing experiment as model of remission bone marrow. Placenta DNA and DNA from patient C in Fig 2A was digested with *Bam*H1 and *Hind*III. The normal DNA was mixed with leukemic DNA at the indicated ratios representing 7.5 μg normal plus 2.25 μg leukemic (1:3.3 or 30%), 7.5 μg normal plus 1.12 μg leukemic (1.0:6.7 or 15%), 7.5 μg normal plus 0.563 μg leukemic (1:13.3 or 7.5%), 7.5 μg normal plus 0.225 μg leukemic (1:33 or 3%), 7.5 μg normal plus 0.113 μg leukemic (1:66 or 1.5%), 7.5 μg normal plus 56.3 ng leukemic (1:133 or 0.75%), 7.5 μg normal plus 22.5 ng leukemic (1:333 or 0.3%), and 7.5 μg normal plus 11.3 ng leukemic (1:666 or 0.15%), respectively. Also individually represented (lanes C and N, respectively) are 2.25 micrograms of leukemic cell DNA and 7.5 μg of normal DNA.

Similar analyses were performed on a total of seven patients (Table 1) in whom morphologically normal clinical remission bone marrows were obtained. Of these seven patients, three exhibited leukemic cells in the remission marrows assessed by the recombinant DNA method (ie, patients No. 1, 2, and 3 of Fig 3 and Table 1). Two controls were required for unambiguous interpretation of these results. First, DNA from the leukemic cells of the same patients was used as a positive control to ensure that the rearranged fragments observed in the remission samples corresponded to the fragments detected in the leukemic cells. Second, normal DNA from the peripheral blood granulocytes of the patient was included as a negative control to verify that any faint rearranged bands were not attributable to the patient's normal genes. In Fig 3, patients No. 2 and 3 displayed rearranged fragments in their remission bone marrow samples (noted with asterisks in lanes R, R_1, and R_2) which were not present in the DNA from normal cells of these patients (lane G). In the R_2 remission sample of patient No. 3, a third rearranged band was present that was not observed in the original leukemic cells or the granulocytes from this patient. This third fragment may have represented a further rearrangement of the immunoglobulin gene which occurred in a subfraction of the leukemic cells.[13] In patients No. 2 and 3, the number of leukemic cells in the remission specimens was estimated as one in 500 and one in 200 nucleated marrow cells, respectively. Patient No. 4 is included to illustrate a clinical remission bone marrow sample with less than one leukemic cell in 500 normal cells as detected in our assay.

DISCUSSION

Using recombinant DNA techniques described above, we have detected one leukemic cell among more than 500

Fig 3. Rearranged DNA fragments of leukemic blasts in remission bone marrows of ALL patients. Each panel depicts a different patient's samples. L denotes DNA from leukemic cells, either presentation or relapse. R denotes remission as defined by morphologic examination (<5% blast cells). Patient No. 3 had two separate remission episodes analyzed. G denotes DNA from the granulocytic cells (included as a negative control for DNA rearrangements). All lanes depict 7.5 μg of DNA digests except patient No. 1, lane L (0.5 μg), and patients No. 3 and 4, lane L (1 μg). Size is indicated at left in kilobases. All samples contained 1 pg pBR322 DNA as a control for hybridization and transfer efficiency. Dots indicate rearranged J_H fragments present in the various samples.

normal nucleated cells in remission bone marrows. In order for this technique to be useful in the analysis of remission bone marrows, a significant number of bone marrows must contain enough leukemic cells to be recognized by the recombinant DNA assay (more than one in 500) but less leukemic cells than sufficient for recognition by morphologic evaluation (1/20). In the initial analyses of the seven patients reported here, three of the bone marrow samples exhibited numbers of leukemic cells in this range. Obviously, further studies are required to define the clinical situations in which this type of analysis will be most useful. The significance of the presence of low numbers of leukemic cells to the clinical status of the patient also remains to be determined. However, for the present, this analysis would appear to be helpful in diagnosis of patients with questionable remission status as assessed morphologically and in patients in whom alternative therapy, such as autologous or allogeneic bone marrow transplantation, is being considered.

ACKNOWLEDGMENT

We thank Ken Hall for providing the patients' samples, Annette Folgueras for technical assistance, and Sandra Smith for assistance in manuscript preparation.

CONCISE REPORT

C-*sis* and C-*abl* Expression in Chronic Myelogenous Leukemia and Other Hematologic Malignancies

By Paolo Romero, Mark Blick, Moshe Talpaz, Edwin Murphy, Jeane Hester, and Jordan Gutterman

Cellular oncogenes have been localized at the breakpoints of characteristic chromosomal rearrangements occurring in certain hematologic malignancies. This has been reported to result in aberrant expression of the involved oncogenes. Over 90% of chronic myelogenous leukemia (CML) is characterized by a reciprocal translocation that brings c-*abl* from chromosome 9 to chromosome 22, and c-*sis* from chromosome 22 to chromosome 9. To investigate the possible role of these two oncogenes in the leukemic process, we studied their expression in a number of fresh samples obtained from patients with various forms of leukemia, by Northern blot analysis using c-*onc* probes. Seven of 24 samples obtained from patients with either CML or chronic myelomonocytic leukemia expressed a normal 4.0-kilobase (kb) c-*sis* transcript. C-*sis* expression was found only in the accelerated/blast phases but not in the chronic phase of CML. All of the CML Philadelphia chromosome-positive (Ph^{1+}) samples expressed an aberrant 8-kb c-*abl* transcript. The expression of c-*sis* in hematopoietic malignancies constitutes a novel finding.

© 1986 by Grune & Stratton, Inc.

IN MORE THAN 90% of the cases of chronic myelogenous leukemia (CML), a characteristic chromosomal abnormality, the Philadelphia (Ph^1) chromosome, is present.[1] This Ph^1 chromosome consists of a shortened chromosome 22 that results from a balanced translocation involving chromosome 9 and 22[2] [t(9;22)(q34;q11)]. The oncogene c-*abl*, normally located on chromosome 9, band q34, near the 9:22 translocation breakpoint, is translocated to chromosome 22.[3] C-*sis*, normally located on chromosome region 22q12.3-q13.1 appears to be at a significant distance from the 9:22 translocation breakpoint and is reciprocally translocated to chromosome 9.[4]

To evaluate the possible role of the c-*abl* and c-*sis* oncogenes in the leukemic process, we have analyzed their expression in a number of hematopoietic cells. We report that a normal size 4-kilobase (kb) c-*sis* transcript is expressed in five of 20 fresh CML samples and in two of four fresh chronic myelomonocytic leukemia (CMML) samples. We have also analyzed these same samples for c-*abl* expression and confirmed that an aberrant 8-kb mRNA species[5,6] is present in all CML Ph^{1+} samples, but not in the CMML samples nor in the samples from other leukemias. The 8-kb c-*abl* mRNA is present in all clinical phases of CML.

MATERIALS AND METHODS

Samples were obtained by leukapheresis. RNA was prepared using the guanidinium/cesium chloride method.[7] Polyadenylated RNA was selected by chromatography on oligo(dT)-cellulose columns. The polyadenylated RNA (5 μg/lane) was size fractionated by electrophoresis in 1.1% agarose gels containing 2.2 mol/L formaldehyde, transferred to nitrocellulose filters with 20× SSC (SSC = 0.15 mol/L sodium chloride, 0.015 mol/L sodium citrate), and hybridized to radiolabeled ^{32}P-DNA probes at 42 °C for 12 hours by a modification of the method described by Thomas.[8] The probes were radiolabeled by nick translation to a specific activity of 1 to 3×10^8 cpm/μg of DNA. The filters were then washed in 0.1× SSC and 0.1% sodium lauryl sulphate at 60 °C for 60 minutes, air dried, and autoradiographed with intensifying screens for two to seven days at −70 °C.

For DNA analysis, restriction endonuclease digestion of high molecular weight DNA was performed as recommended by the supplier, and blot hybridization was carried out as described by Southern.[9] For our *sis* hybridization experiments, we employed an *Eco*R1/*Pst*1 fragment of clone L33,[10] corresponding to the 5′ region of c-*sis* and a *Bam*HI fragment of clone L33 corresponding to the 3′ end of c-*sis*. The probes for our *abl* hybridization experiments were derived from subclones of c-*abl* containing cosmids. We utilized an *Eco*R1/*Bam*HI fragment corresponding to the most 5′ v-*abl* hybridizing region and a *Hind*III/*Eco*R1 fragment corresponding to the 3′ region of c-*abl*.[3] In the Northern experiments, only the 3′ c-*sis* probe and the 5′ c-*abl* probe were used. In the Southern experiments, all four probes were used.

RESULTS

As shown in Fig 1 and Table 1, we detected a 4-kb c-*sis* transcript in three samples obtained from patients in the accelerated phase (AP) of CML (CML-AP), in two samples obtained from patients in the lymphoid CML blast crisis (BC) phase (CML-BC), and in the K562 cell line, derived from a patient with CML-BC. C-*sis* expression was of low intensity and comparable with the level detected in the Hut 102 cell line, derived from a patient with cutaneous T cell lymphoma and known to express c-*sis*.[11] We also found c-*sis* expressed in two samples from patients with CMML, a disorder frequently confused with CML, and often called Ph^1-negative (Ph^{1-}) CML. With the exception of one patient with CML-BC, all the samples that expressed the 4-kb c-*sis* transcript also expressed a less intense 3-kb species as reported by others (Fig 1).[12] An analysis of the DNA using the restriction enzymes *Eco*RI and *Bgl*II and probes from both ends of the c-*sis* gene disclosed no DNA amplifications or rearrangements in those samples that expressed c-*sis* (data not shown).

Fig 2 and Table 1 show our results using the c-*abl* probe. An aberrant 8-kb transcript was expressed in all Ph^{1+} CML

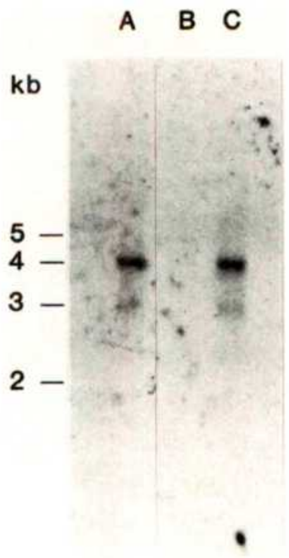

Fig 1. Northern blot analysis using a c-*sis* probe demonstrating c-*sis* expression in fresh CML-AP (lane A) and in the control Hut 102 cell line (lane C). C-*sis* is not expressed in a fresh CML-CP (lane B). 5-kb corresponds to 28s rRNA and 2-kb to 18s rRNA, which were used as molecular size markers.

samples. This 8-kb c-*abl* transcript was not detected in fresh samples obtained from patients with Ph^{1-} diseases: CMML, chronic lymphocytic leukemia (CLL), acute myelogenous leukemia (AML), and the Hut 102 cell line. The two normal c-*abl* transcripts of 7- and 6-kb were present in both Ph^{1+} and Ph^{1-} samples with the exception of two samples obtained from patients with CML in blast crisis. The 8-kb transcript was the predominant c-*abl*–related mRNA species in those samples expressing it. In four of six samples obtained from patients with CML-BC, the expression of this abnormal 8-kb transcript was increased to levels comparable with those in the K562 cell line, known to have an amplified c-*abl* gene.[13] Analysis of the DNA from these fresh samples, using the restriction enzymes *Eco*RI and *Bgl*II and probes from both the 5′ and 3′ ends of the c-*abl* gene disclosed no c-*abl* amplifications or rearrangements (data not shown).

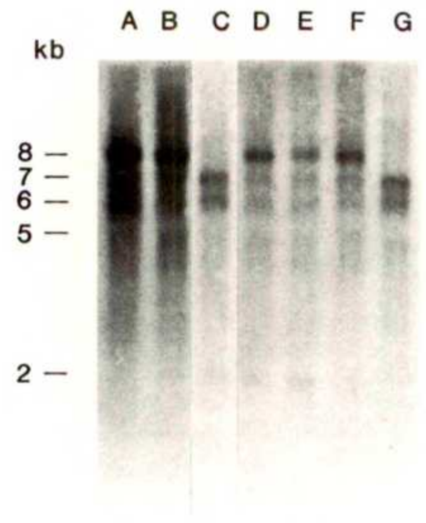

Fig 2. Northern blot analysis demonstrating an aberrant 8-kb c-*abl* transcript in the K562 cell line (lane A), a fresh CML-BC (lane B), CML-AP (lane D), two fresh CML-CP (lanes E and F). A 6- and 7-kb c-*abl* transcript is present in all samples including a fresh CMML (lane C) and the Hut 102 cell line (lane G). 5-kb corresponds to 28s rRNA and 2-kb to 18s rRNA, which were used as molecular size markers.

DISCUSSION

C-*sis*, the cellular homologue of the simian sarcoma virus oncogene, is the structural gene for the B chain of platelet-derived growth factor (PDGF),[14,15] the major mitogen of human serum. C-*sis* expression has been found in osteosarcomas, fibrosarcomas, and gliomas, but not in hematologic malignancies with the exception of the cell line Hut 102.[11,12] The mitogenic properties of PDGF may be involved in tumor development, according to an autocrine model in which the neoplastic cells proliferation is driven by growth factors produced by the tumor itself.[16] Since PDGF is reported to have mitogenic effects on hematopoietic cells[17] as well as hematopoietic microenvironment cells[18] when exogenously administered, perhaps the product of c-*sis* in CML is secreted and does have a direct dysregulatory effect on hematopoiesis. Alternatively, the product of c-*sis* in CML is not secreted and the neoplastic cells are rendered mitogenically competent by PDGF's effects on internal cellular structures as suggested by others studying an osteosarcoma cell line.[19] In any event, the role of c-*sis* in CML and CMML remains speculative at present, and its expression may be a consequence of the neoplastic state, rather than being a causal factor. The fact that c-*sis* is expressed in Ph^{1-} disease suggests that its expression is not a consequence of the 9:22 translocation. It is also of note that c-*sis* expression was found only in the accelerated or blast phases, but not in the chronic phase of CML (Table 1), raising the possibility that it may have a role in the progression of the disease.

The finding of an aberrant 8-kb c-*abl* transcript in Ph^{1+} CML has been reported previously.[5,6] We have extended these observations to include more patient samples and report that the 8-kb aberrant transcript is present in all patients and in all phases of the disease. Other investigators have recently demonstrated in the K562 cell line and fresh CML samples the presence of an abnormal c-*abl* protein with tyrosine kinase activity that is not present in normal cells.[20] It is conceivable that this protein is encoded by the 8-kb c-*abl* transcript. The nature of the 8-kb mRNA has been recently clarified by cDNA cloning.[21] It appears to be a fused transcript of the *bcr* gene of chromosome 22 and of the translocated c-*abl* gene. Our study confirms the uniform size of the aberrant transcript in spite of variable breakpoints on both chromosomes.[22] This suggests that the splicing of the large primary transcript must occur at common donor-acceptor sites.

ACKNOWLEDGMENT

The authors thank Dr John Groffen for the c-*abl* probes, Dr Steven F. Joseph for the c-*sis* probes, and Lydia Morris for help in the preparation of the manuscript.

CONCISE REPORT

Monoclonal Antibody 12-8 Recognizes a 115-kd Molecule Present on Both Unipotent and Multipotent Hematopoietic Colony-Forming Cells and Their Precursors

By Robert G. Andrews, Jack W. Singer, and Irwin D. Bernstein

A monoclonal antibody, 12-8, prepared against KG-1a cells, recognizes an approximately 115-kd cell surface antigen and reacts with 3% to 4% of bone marrow cells, including most of the blast cells. The antigen is not expressed on peripheral blood cells. Marrow cells expressing 12-8 collected by fluorescence-activated cell sorting contained nearly all of the unipotent (CFU-GM, BFU-E) and multipotent (CFU-MIX) colony-forming cells. The isolated 12-8 positive marrow population also contained precursors of these colony-forming cells. In a two-stage long-term marrow culture system employing irradiated allogeneic marrow adherent cells, 12-8 positive cells produced both unipotent and multipotent colony-forming cells for ten weeks. Moreover, the output of colony forming cells substantially exceeded the input. Antibody 12-8 appears useful for analysis and possibly enrichment of hematopoietic progenitor cells that include colony-forming cell precursors.

© 1986 by Grune & Stratton, Inc.

NUMEROUS monoclonal antibodies which recognize antigens expressed by normal myeloid cells of different lineages and at specific stages of maturation have now been prepared.[1,2] These antibodies are potentially useful for separating myeloid cells at distinct stages of differentiation and progenitor cells at different levels of commitment.

In the present article, we describe an antibody, 12-8, which recognizes an antigen of approximately 115 kilodaltons (kd) and reacts with a minor subset of bone marrow cells containing virtually all unipotent and multipotent colony-forming cells. Of significance is the observation that this minor population also contains cells that appear to give rise to colony-forming cells in a long-term bone marrow culture system.[3]

MATERIALS AND METHODS

Production of antibody 12-8. Seven-week-old Balb/c mice were immunized intraperitoneally with 3×10^6 KG-1a cells on days 9 and 28, and with 3×10^6 cells intravenously on day 42. On day 45, spleen cells were fused with SP2/0 myeloma cells using previously described techniques.[4] Hybrids secreting antibody that bound to KG-1a but not to peripheral blood granulocytes, in a ^{125}I-staphylococcal protein-A binding assay,[5] were formally cloned.[4] Selected clones were expanded and unfractionated culture supernatants were obtained for further studies. Antibody 12-8 was determined to be an IgM molecule using described immunodiffusion techniques[4] and was cytotoxic for KG-1a cells in the presence of complement.[4]

Peripheral blood and bone marrow cells. Samples of peripheral blood and bone marrow were obtained from normal healthy volunteers following informed consent. Peripheral blood lymphocytes, monocytes, granulocytes, red cells, and platelets were isolated as previously described.[4] The lymphocyte populations contained approximately 5% B cells and 82% T cells as determined by reactivity with anti-T cell (10.2, CD-5)[1] and anti-B cell (1F5, CD-20)[2] antibodies, and the monocytes were 65% reactive with an anti-monocyte (5F1, CDw14)[1,4] antibody. Samples of thymocytes were kindly provided by Dr P. Martin, Fred Hutchinson Cancer Research Center, Seattle.

Immunofluorescence assays and cell sorting. Reactivity of 12-8 with different cell types was determined by indirect immunofluorescence, and stained and unstained cells were separated by fluorescence activated cell sorting (FACS) as previously described.[6]

Hematopoietic progenitor assays. Unipotential colony-forming cells (CFC), BFU-E and CFU-GM, and multipotent CFCs, CFU-MIX, were cultured as previously described.[6,7] Long-term cultures were performed using Ambitube (Miles Scientific, Naperville, Ill) culture tubes with established confluent marrow adherent cell layers

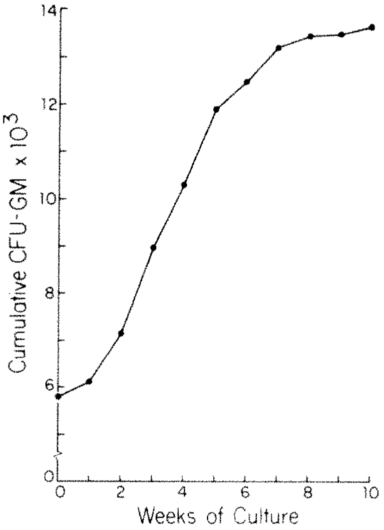

Fig 1. Cultures established with 1.2×10^5 12-8 positive marrow cells containing 5,789 CFCs were assayed weekly for the presence of CFU-GM in culture supernatants. Total CFU-GM present each week equaled CFU-GM/volume removed/(volume removed/volume in culture). Cumulative CFU-GM equals the sum of weekly mean total CFU-GM over 10 weeks of culture.

that have been irradiated (1,148 ± 209 cGy) as previously described.[3]

Radioimmunoprecipitation. KG-1a cells (2 × 10^7) were surface labeled with ^{125}I by the iodogen method.[8] They were lysed with 0.5% NP-40 in the presence of protease inhibitors, and immunoprecipitated using Sepharose 4B (Pharmacia, Piscataway, NJ) coupled rabbit antibodies to mouse immunoglobulin,[9] and analyzed by polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate (SDS).[10] The control antibody, K32, which recognizes the transferrin receptor, was prepared in our laboratory (Fig 1).

RESULTS

Reaction of antibody 12-8 with hematopoietic cells. Antibody 12-8 did not react with peripheral blood lymphocytes, monocytes, granulocytes, platelets, RBCs, or thymocytes in indirect immunofluorescent assays (data not shown). However, a minor portion of normal bone marrow cells were stained. In two experiments, positively and negatively stained marrow cells were separated by fluorescence-activated cell sorting (FACS). The sorting windows for the 12-8 positive population contained 3.5% to 4.0% of analyzed cells, and the isolated 12-8 stained population was highly enriched for the least mature (blast) cells present in marrow (Table 1).

Reaction of antibody 12-8 with hematopoietic progenitors. Marrow cells that were stained or unstained by antibody 12-8 were separated by FACS and analyzed for their ability to form colonies in vitro (Table 2; day 0, Experiments 1 and 2). Virtually all of the sorted colony-forming cells were contained in the 12-8 stained population and accounted for the majority of all colony-forming cells, both unipotent and multipotent, present in unseparated marrow.

Separated cells were also cultured in a long-term culture system. Because of the paucity of isolated 12-8 bearing cells and the possibility that this population lacked accessory cells required for establishment of long-term cultures, each of the separated as well as the unseparated cell populations were placed over previously established irradiated allogeneic marrow adherent cell layers[3] (Table 2). *Shown in boxes, day 0 (experiments 1 and 2) are the mean ± SEM number of colony-forming cells of each type detectable in replicate cultures in semisolid medium. On days 14, 21, and 28 below, the number of colony-forming cells obtained from suspension culture supernatants is shown. In experiment 1, suspension cultures were established with either 1.2 × 10^5 12-8 positive cells; 2.0 × 10^6 12-8 negative cells; or 2.0 × 10^6 unseparated cells per tube. The 12-8 positive sorting window included 3.5% of cells and the 12-8 negative sorting window encompassed 95% of marrow cells analyzed. In experiment 2, cultures were established with 1.25 × 10^5 12-8 positive cells; 3 × 10^6 12-8 negative cells; or 3.2 × 10^6 unseparate cells per tube. The 12-8 positive sorting window included 4.0% of cells and the negative sorting window included 94% of marrow cells analyzed.

†Results of cultures from a single tube.

cultures of isolated 12-8 positive marrow cells produced, over a 4-week period, a greater number of colony-forming cells than did supernatants from cultures of either unseparated or 12-8 negative cells. This was despite the fact that the cultures of 12-8 positive cells were initiated with a significantly smaller number (approximately 5%) of cells than used to initiate the other cultures. In addition, the 12-8 positive cells produced CFU-GM over a 10-week period. The cumulative number of CFU-GM produced by a single 12-8 long-term culture initiated with 1.25×10^5 cells over this period shown in Fig 1 demonstrates the total output of the culture substantially exceeded the input of colony-forming cells (input: 5,789; output: 14,354). Not shown is the growth of BFU-E (25, 25 and 0 colonies) and CFU-MIX (8, 0, and 8) from cells harvested at weeks 8, 9, and 10, respectively.

Biochemistry. The antigen recognized by the antibody 12-8 has a molecular weight of approximately 115 kd under reducing and nonreducing conditions (Fig 2) as demonstrated by radioimmunoprecipitation from ^{125}I surface-labeled KG-1a cells.

DISCUSSION

This article demonstrates that the myeloid differentiation antigen recognized by the 12-8 antibody is expressed by hematopoietic CFCs and their precursors detectable in long-term marrow culture. The presence of 12-8 antigen on precursors of CFCs is suggested by the ability of 12-8 positive cells to give rise to CFCs over an extended period of time with a substantially larger output of CFCs than were present when the cultures were started.

On the basis of cellular distribution and molecular weight, the 12-8 antigen may be the same as that identified by Civin et al[11] and Tindle et al.[12,13] These authors described antibodies MY-10 and B1-3C5, respectively, that recognized molecules with approximate molecular weights of 115 to 120 kd present on a minor population of immature hematopoietic cells, including CFU-GM, BFU-E, and CFU-MIX. Few other differentiation antigens have been described which are present on both unipotent and multipotent hematopoietic progenitors. Examples include an antigen identified by L4F3 and an antibody of similar specificity, MY-9[14]; an antigen recognized by RFB-1[15]; as well as HLA-DR antigens.[16] In contrast, the precursors of colony-forming cells lack the L4F3 antigen and may express some[17] but not all class II antigens,[18,19] while the expression of other antigens has not yet been evaluated. Most important, the present studies demonstrate the presence of the 12-8 antigen on the precursors of colony-forming cells as well as their colony-forming progeny.

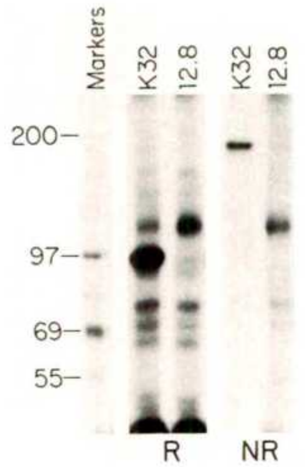

Fig 2. Immunoprecipitation by antibody 12-8 of a 115-kd antigen from surface ^{125}I-labeled KG-1a. The antibodies used were 12-8, lane 3 and lane 5; and control antibody K32 against the transferrin receptor, lanes 2 and 4. The immunoprecipitation samples were either reduced (lanes 2 and 3) or not reduced (lanes 4 and 5) and electrophoresed on 7.5% SDS polyacrylamide gel. In lane 1, ^{14}C-labeled protein markers are shown.

Although the function of the antigen recognized by 12-8 remains to be determined, this antibody appears useful for analysis of early hematopoietic development. By combining negative selection methods, eg, using antibody L4F3 and complement, and positive selection with 12-8, it now may be possible to highly enrich, if not purify, primitive colony-forming cell precursors in order to examine the conditions which lead to their proliferation and/or differentiation.

CORRESPONDENCE

NEONATAL ALLOIMMUNE THROMBOCYTOPENIC PURPURA AND CONGENITAL PORENCEPHALY ASSOCIATED WITH A NEW MATERNAL ANTIPLATELET ANTIBODY

To the Editor.

I have read with interest the paper of Friedman and Aster entitled "Neonatal Alloimmune Thrombocytopenic Purpura and Congenital Porencephaly in Two Siblings Associated With a 'New' Maternal Antiplatet Antibody" in the June issue of *Blood*[1]

The mother's serum most likely had antibodies to platelet glycoproteins (GP) IIb/IIIa since her serum failed only to react with platelets from patient with type I Glanzmann's thrombasthenia.[2] It has been shown that autoantibodies to GP IIb/IIIa could be present in some ITP cases, especially chronic ones[3] If her serum would also react with the platelets of her oldest son, whose father was different from her present husband, this would most likely indicate that her antibodies were not specific to a "new" platelet antigen but were to GP IIb/IIIa, which is found some ITP cases.

Since we have shown that antiplatelet antibodies were persistent with short platelet survival in ITP patients in remission,[4] I would suggest that her antibodies were reminiscent from her asymptomatic ITP, causing problems related to thrombocytopenia in her fetuses.

To the Editor·

Dr Ozsoylu suggests that serum Pen from the mother of two infants with neonatal alloimmune thrombocytopenic purpura which we describe in our recent paper[1] is an autoantibody related to asymptomatic maternal ITP. We believe that this interpretation is unlikely to be correct for several reasons. First, as stated in our report, Mrs Pen did not ever have thrombocytopenia, purpura, or bleeding problems. Second, her serum did not react with her own platelets and thus did not contain an antiplatelet autoantibody. Mrs Pen's serum also does not react with platelets from her normal sister or with platelets from an unrelated Latin American woman with posttransfusion purpura whom we have studied more recently. The data support our conclusion that serum Pen recognizes a previously undescribed high-frequency platelet alloantigen.

ANNOUNCEMENTS

SECOND ANNUAL HEMATOLOGY-ONCOLOGY SYMPOSIUM

Amelia Island, Florida
April 4–6, 1986

A conference designed for the practicing hematologist/oncologist. Up-to-date information with practical application and quality teaching.

Course Directors: Craig S. Kitchens, M.D., and Warren A. Ross, M.D.
Guest Faculty: Victor J. Marder, M.D., and Howard Ozar, M.D.
Special Guest & Speaker: Eugene A. Stead, M.D.
For further information contact: Craig S. Kitchens, PO Box 2715, Gainesville, FL 32601

REGISTRY OF CLINICAL TRIALS OF COAGULATIVE-REACTIVE AGENTS IN CANCER

The International Committee on Thrombosis and Hemostasis has established a Subcommittee on Hemostasis and Malignancy. This Subcommittee maintains a registry of therapeutic trials in which anticoagulants, platelet antagonists, inhibitors of prostaglandin synthesis, or modifiers of fibrinolytic reactions are being tested in human malignancy.

Information on such studies may be sent to Leo R. Zacharski, MD, VA Hospital, White River Junction, Vermont 05001.

SHORT COURSE IN MEDICAL AND EXPERIMENTAL MAMMALIAN GENETICS

July 7–18, 1986
Bar Harbor, Maine

Conducted by The Jackson Laboratory and Johns Hopkins University. Lectures covering the entire field are supplemented by methodologic workshops in cytogenetics, biochemical screening, linkage analysis, and molecular genetics, as well as by demonstrations of mouse mutants and problems in clinical genetics. Held at The Jackson Laboratory. Inquiries and applications should be made to: Victor A. McKusick, MD, 292 Carnegie Bldg, Johns Hopkins Hospital, 600 N Wolfe St, Baltimore, MD 21205; or to Thomas H. Roderick, PhD, c/o Training & Education Office, The Jackson Laboratory, Bar Harbor, ME 04609.

Blood, Vol 67, No 3 (March), 1986: p 847

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to BLOOD. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: BLOOD will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the BLOOD Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in BLOOD represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a $50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to.

John W. Adamson, MD, Editor
BLOOD
University District Building—Room 320
1107 NE 45th St
Seattle, WA 98105

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1986, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $30.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of BLOOD will assume that the authors of research papers published in BLOOD are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and *two* complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information. (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least 1/12 inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus.* (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors Supply only first page number for each reference. References to abstracts and letters must be identified as such

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

POORLY DIFFERENTIATED NEOPLASMS AND TUMORS OF UNKNOWN ORIGIN

Edited by

MEHMET F. FER, M.D., ROBERT K. OLDHAM, M.D., and
F. ANTHONY GRECO, M.D.

Clinical Oncology Monographs Series
Series Editors: **John W. Yarbro, M.D., Ph.D., Richard S. Bornstein, M.D., and Michael J. Mastrangelo, M.D.**

This important new book reviews in detail the diagnostic techniques, clinical syndromes, and therapeutic approaches to poorly differentiated neoplasms and tumors of unknown origin

The interdisciplinary coverage in the text includes comprehensive discussions of the role of the pathologist in the evaluation of these malignancies, followed by general diagnostic techniques, tumor markers, commonly seen clinical syndromes, and new experimental methods

Poorly Differentiated Neoplasms and Tumors of Unknown Origin will aid the oncologist, pathologist, internist, and hematologist with the difficult classification and selection of therapy for patients with these disorders.

CONTENTS: Contributors *Mehmet F. Fer, F. Anthony Greco, and Robert K Oldham,* Introduction *Bruce Mackay and Nelson G Ordóñez,* The Role of the Pathologist in the Evaluation of Poorly Differentiated Tumors and Metastatic Tumors of Unknown Origin *Raymond W Ruddon,* Immunologic and Biochemical Markers in the Diagnosis and Management of Poorly Differentiated Neoplasms and Cancers of Unknown Primary. *Q Scott Ringenberg and John W Yarbro,* Presentations and Clinical Syndromes of Tumors of Unknown Origin *Matthew L. NATIONAL INSTITUTES OF HEALTH
PUBLIC HEALTH SERVICE
DEPARTMENT OF HEALTH AND HUMAN SERVICES
Opening Date: March 1, 1986 / Closing Date: March 31, 1986
(All applications must be postmarked before closing date)

DIRECTOR, NATIONAL INSTITUTE OF DIABETES AND DIGESTIVE AND KIDNEY DISEASES

The National Institutes of Health invites nominations and applications for the position of Director, National Institute of Diabetes and Digestive and Kidney Diseases, (NIDDK). This Institute conducts, fosters, and supports research and research training on the prevention, management, and cure of diabetes and related endocrine and metabolic diseases; kidney, urologic and blood diseases; and digestive diseases. Programs encompass intramural laboratory research and extramural (grants and contracts) activities in fundamental diabetes, digestive and kidney disorders.

This is a Civil Service position in the Senior Executive Service (SES), with a salary range from $61,296 to $68,700 per annum depending on qualifications. Candidates may be eligible for Physicians Comparability Pay up to $10,000 per year. Alternately, candidates may be eligible for appointment in the Commissioned Corps of the U.S. Public Health Service. The SES individual selected, if not presently in the SES, must serve a one-year probationary period.

The mandatory qualifications are: (1) meet the minimum educational requirements for Medical Officer, GS-602, or Health Scientist, GS-601, or equivalent combination of experience and training, which demonstrates a broad knowledge and understanding of major public health problems; and (2) have research experience and knowledge of research programs in one or more areas related to diabetes, digestive and kidney disorders. In addition, candidates must meet the following managerial/executive qualifications: experience in the leadership/management of a basic or clinical research program, demonstrating competence to assume leadership responsibilities in: (1) assuring that national and agency goals and priorities are considered in carrying out the functions and responsibilities of the organization; (2) establishing and maintaining relationships with key individuals and groups outside the organization; (3) directing and guiding programs and projects, including long-term and short-term planning and establishing objectives and priorities; (4) establishing procedures for the development and defense of the organization's budget, and allocating fiscal and personnel resources to support program implementation; (5) developing processes and overseeing activities to assure the fair and equitable employment of qualified persons, and implementing EEO/Affirmative Action objectives; (6) developing and implementing procedures for monitoring program performances, including periodic analysis and evaluation.

Candidates who meet the mandatory requirements will be further evaluated by the Search Committee on the following factors: additional managerial/executive qualifications; scientific reputation/peer recognition; training and education; honors and awards; and communications and interpersonal skills.

Applications (Personal Qualifications Statement, SF-171) are to be sent to Helen C. Stafford, Executive Secretary, Search Committee for Director, NIDDK, National Institutes of Health, Building 1, Room 19, Bethesda, Maryland 20892. For further information, contact her on (301) 496-4197. A current curriculum vitae and bibliography must accompany all applications. Applications of women and/or minority group members are especially solicited.

PROGRESS IN HEMATOLOGY

Volume XIV

Edited by

Elmer B. Brown, M.D.

A REVIEW FROM THE SILVER ANNIVERSARY ISSUE:

"As the scientific literature expands and the rate of accumulation of new information accelerates, the need for critical synthesis of the literature is more and more strongly felt . . . For more than two decades, ***Progress in Hematology*** *has served the useful purpose in a field that includes hematology in its broadest sense...intended for the hematologist, in research, practice or training, who wants to have an overview of the areas with which he is not dealing directly."*

— JAMA

For Fastest Service CALL TOLL-FREE 1-800-321-5068. To Place An Order From Florida, Hawaii, Or Alaska CALL 1-305-345-4100. In The U.K. CALL (01) 300-0155. Send payment with order and save postage and handling. Prices are in U.S. dollars and are subject to change without notice.

Progress in Hematology, Volume XIV continues in the tradition of previous volumes by providing thorough coverage of the most important clinical and research topics in the field.

Authorities from the United States and abroad review their areas of special expertise to provide the guidance needed to both stay abreast of the rapid changes in hematology and to educate students about its tools and concepts.

This informational synthesis will appeal to medical students, residents, fellows, clinical and laboratory physicians interested in hematology, medical teachers and investigators, and all medical libraries. Through careful reading, the volume offers the ability to identify, evaluate, and place in perspective these signifcant contributions to the literature of hematology.

COOLEY'S ANEMIA FOUNDATION, INC. RESEARCH FELLOWSHIPS

The Cooley's Anemia Foundation, Inc., invites applications for fellowships to both postdoctoral fellows and junior faculty members interested in the field of Cooley's anemia with stipends of up to $15,000. The deadline for receipt of applications is May 1, 1986. Awards will be made by June 15, 1986, and funding will begin July 1, 1986, for one year with the possibility of renewal for a second year.

For application forms and further information write:

Mr. Michael C. DiFilippo, National Executive Director, Cooley's Anemia Foundation, Inc., 105 East 22nd Street, Suite 911, New York, New York 10010. Telephone: (212) 598-0911.

Assistant Professor and Assistant Medical Director. St. Paul Region, American Red Cross Blood Services and University of Minnesota Hospitals Blood Bank.

A position is available for a physician, board certified or board eligible, in clinical pathology with blood banking fellowship or one years experience in clinical pathology beyond residency. Candidates should have experience in transplantation and research.

This individual in this position will be involved in the teaching of Blood Banking/Immunohematology through formal courses and informal supervision and teaching of medical students, residents, fellows, and allied health students. Particular emphasis in the teaching and research programs will be on new knowledge and technology relating to tissue and organ procurement, preservation and transplantation. Independent basic or clinical research relating to these areas is expected. This position will serve as Assistant Director of the Regional Blood Services and the University Hospitals Blood Bank and will assume partial responsibility for the daily operations of these facilities.

This position carries a tenure track faculty appointment in the medical school and involves major research and teaching commitments. Applicants should send curriculum vitae and three letters or recommendations to Edward Scott, M.D , Dept of Laboratory Medicine and Pathology; Box 198 Mayo; 420 Delaware St SE; Mpls, Mn 55455. Deadline for receipt of applications is April 15, 1986. The University of Minnesota is an equal opportunity educator and employer and specifically invites and encourages applications from women and minorities.

Frontiers in Basic Sciences That Relate to
Heart, Lung, and Blood Diseases Symposium:

BASIC MECHANISMS OF MESENCHYMAL CELL GROWTH

National Institutes of Health, Bethesda, Maryland
June 5 and 6, 1986

Sponsored by·
The National Heart, Lung, and Blood Institute of the
National Institutes of Health

This symposium is one in a series of conferences on "Frontiers in Basic Sciences That Relate to Heart, Lung, and Blood Diseases" conducted by the National Heart, Lung, and Blood Institute to capitalize on and transfer the achieved progress in basic science disciplines to clinical research problems At this symposium, leading experts in the field will present their views on the present state of the science, the problems facing current understanding, and anticipated future developments in basic mechanisms of mesenchymal cell growth.

The symposium will be cochaired by Dr. Ronald G Crystal of the National Heart, Lung, and Blood Institute and Dr George R. Martin of the National Institute of Dental Research Presentations will be structured around the following topics. Classification of Growth Factors and Models of Growth Control; Exogenous Versus Autocrine Signals, Defined Growth Signals, including Platelet-Derived Growth Factor, Fibroblast Growth Factor-Endothelial Cell Growth Factor Family, Fibronectin, Insulin-Like Growth Factors, Transforming Growth Factors Alpha and Beta, and Interleukin-1, Regulation of Expression of the Genes for Growth Signals, and Responses of Mesenchymal Cells to Growth Signals, including Receptors for Growth Factors, Events Following Stimulation by Growth Factors, and Nonproliferative Responses to Growth Factors. Presentations by noted experts will be followed by open discussion by all participants.

3 Volumes in the BRISTOL-MYERS CANCER SYMPOSIA Series

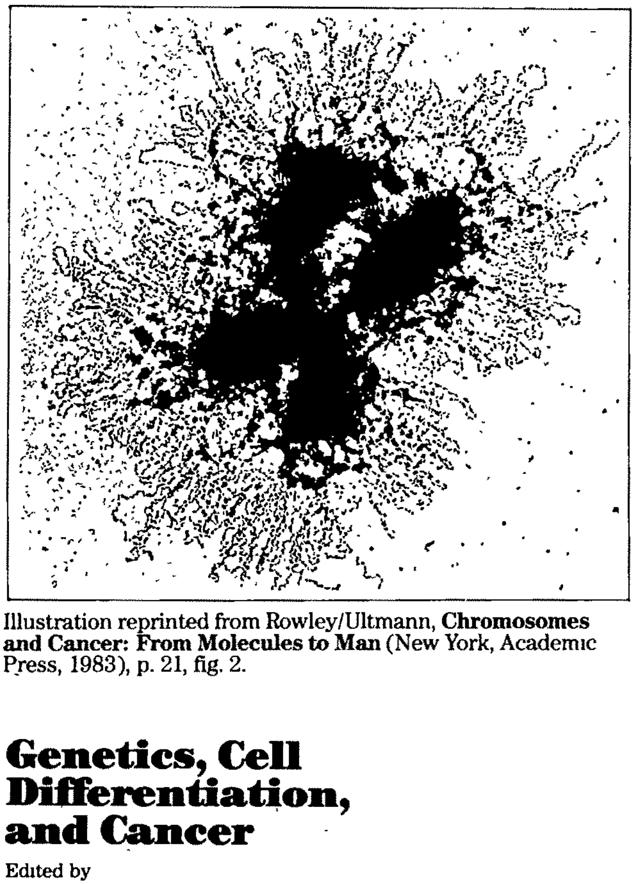

Illustration reprinted from Rowley/Ultmann, **Chromosomes and Cancer: From Molecules to Man** (New York, Academic Press, 1983), p. 21, fig. 2.

Genetics, Cell Differentiation, and Cancer

Edited by
PAUL A. MARKS

FROM THE PREFACE: This volume provides elegant testimony to the importance of studies on prokaryotes, simple eukaryotes, organisms such as yeast, and *Drosophila* in providing insight into the nature of cancer. The first series of papers in these proceedings report on studies of DNA replication, DNA structure, RNA synthesis, and control of gene expression. Subsequent papers review recent research on oncogenes and their role in inducing malignant growth.

CONTENTS (Section Headings): Editor's Foreword. Foreword. Abbreviations. Introduction: Genetics, Cell Differentiation, and Cancer. Gene Structure and Expression. Cancer Genes and Viruses. Each chapter includes references Index.

December 1985 232 pp. $25.00
ISBN: 0-12-473060-4

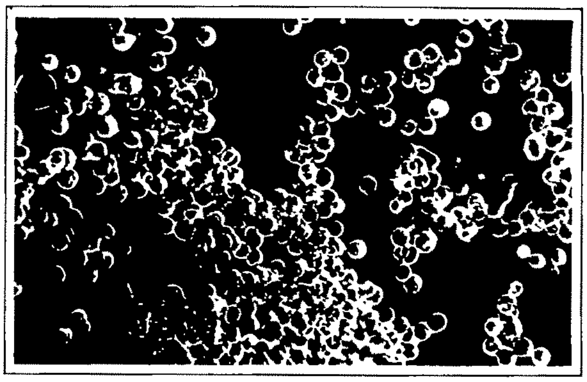

Illustration reprinted from Rosenberg/Kaplan, **Malignant Lymphomas: Etiology, Immunology, Pathology, Treatment** (Orlando, Academic Press, 1982), p 14, fig. 7.

Chromosomes and Cancer
FROM MOLECULES TO MAN

Edited by
JANET T. ROWLEY
JOHN E. ULTMANN

The outstanding features of this book include:

- the first research report on human oncogenes which discusses the cloning of the chromosome translocation breakpoint in Burkitt's lymphoma;
- the most current review of chromosome changes in a variety of human and mouse tumors;
- data on oncogene localization using somatic cell hybrids;
- current techniques for *in situ* hybridization with autoradiography and immunologic approaches.

1983 357 pp. $44.50 ISBN: 0-12-600250-9

Malignant Lymphomas
Etiology, Immunology, Pathology, Treatment

Edited by
SAUL A. ROSENBERG
HENRY S. KAPLAN

FROM THE FOREWORD: This volume discusses the current knowledge of immunologic markers, including the use of hybridomas to produce monoclonal antibodies to tumor antigens. Also, the results of an international comparison of the major pathologic classification systems for lymphomas are detailed.

1982 682 pp. $60.00 ISBN: 0-12-597120-6

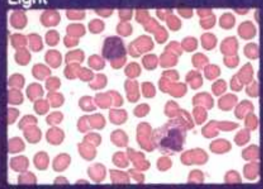
Finally, a better hematology slide stainer.

The new Wescor Model 7100 AEROSPRAY™ Stainer. Its unique, patented staining process produces consistently uniform slides in minutes. Here's what makes the AEROSPRAY Stainer so advanced: fresh stain and reagents are sprayed as an **atomized fine mist** on slides mounted in a rotating carousel within a closed chamber. The end result: clean, high-quality slides with uniform intensity time after time.

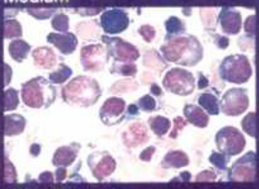
The Model 7100 can process from 1 to 12 slides in three minutes. It's a versatile performer too…programmable for 5 different stain intensities plus a bone marrow selection.

Light

Medium



Dark



Bone-Marrow

You'll also be pleased with other features of the AEROSPRAY 7100 including a self-cleaning cycle, microprocessor-based timing and control functions, and neat, convenient stain pack loading. On top of all that, the 7100 is virtually maintenance free.

For more details on the biggest advance in slide staining in years, contact WESCOR at 459 S. Main Street, Logan, Utah 84321. Telephone (800) 453-2725.

WESCOR

A leader in innovative clinical instrumentation since 1973.

BRAVO!

Introducing the Versatile Performer New COAG-A-MATE® XC

The new COAG-A-MATE XC delivers the versatile, reliable performance essential for today's coagulation testing needs.

- **Performance that's practical** — Does all key coagulation tests: PT, APTT, TT (thrombin time), fibrinogen and factor assays. Automated performance for rapid throughput.
- **Performance you can applaud** — Advanced programming allows all testing parameters to be temporarily or permanently modified by operator, with results expressed in %, ratio, seconds or mg/dl. Holds up to 15 standard curves in permanent memory.
- **Performance you can afford** — Equipped with numerous labor- and time-saving features, like semiautomated pump calibration and rapid priming/depriming, COAG-A-MATE XC is economical to operate and attractively priced for today's mid-sized laboratory.
- **Performance you can depend on** — Two separate self-checking diagnostic programs help ensure reliable performance and trouble-free operations.

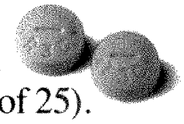
derate Rescue

WELLCOVORIN®
TABLETS
(leucovorin calcium)

The First Leucovorin Rescue With Oral Convenience

As a result of advanced technology,
Wellcovorin is the first leucovorin calcium available in convenient tablet form.
With Wellcovorin Tablets, no reconstitution of vials, mixing of special solutions,
or cumbersome breaking of ampuls is necessary.

For greater flexibility in oral dosing, Wellcovorin Tablets come in two sizes: 5 mg (scored, bottles of 100) and 25 mg (scored, bottles of 25).



Consider Enhanced Quality of Life:

Often discharged from the hospital earlier, many patients can complete their course of therapy on an outpatient basis and return to a more normal, comfortable lifestyle sooner.

Consider Less Costly Care:

Mg for mg, Wellcovorin Tablets are less expensive than injectable leucovorin. Plus, with Wellcovorin Tablets, hospital stays are often shorter and clinic visits less frequent.

Consider Greater Patient Comfort:

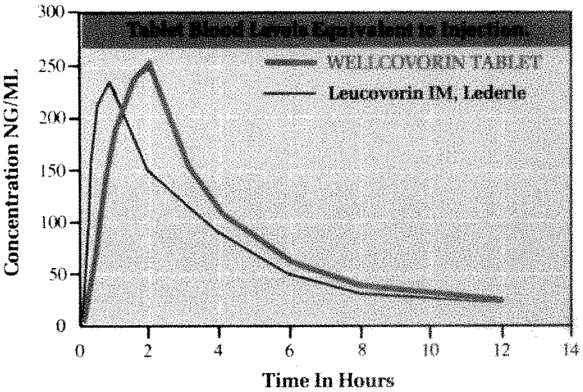
Patients no longer need to drink special liquid formulations or endure a series of painful needle punctures. Patients simply take the prescribed number of Wellcovorin Tablets with water.

Burroughs Wellcome Co.
Wellcome Research Triangle Park, NC 27709

Consider Assured Blood Levels:

Wellcovorin Tablets are bioequivalent to equal amounts of injectable leucovorin, whether it is administered intravenously or intramuscularly (peak serum concentrations are reached after approximately two hours).

Blum MR, Guaspari A, Liao SHT, et al. Bioavailability and pharmacokinetics of oral and parenteral leucovorin. 33rd National Meeting Pharm Sci, San Diego, California, 1982, 12(2):175



Average serum folates after single 15 mg dose of leucovorin administered either IM or orally. Adapted from Blum, et al

Please see brief summary of prescribing information on next page.

WELLCOVORIN® TABLETS
(leucovorin calcium)
Leucovorin in convenient
5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m^2 orally or parenterally followed by 10 mg/m^2 orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m^2 every three hours until the serum methotrexate level is below 5×10^{-8}M.[1,2]

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e. trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[3,4,5]

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

Monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

Monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

for information contact:

MACOP-B

Drug Doses and Treatment Schedule for MACOP-B†

Drug	Dose	Route	Timing
Methotrexate††	400 mg/m²	IV	Weeks 2, 6, 10
Doxorubicin	50 mg/m²	IV	Weeks 1, 3, 5, 7, 9, 11
Cyclophosphamide	350 mg/m²	IV	Weeks 1, 3, 5, 7, 9, 11
Vincristine	1.4 mg/m²	IV	Weeks 2, 4, 6, 8, 10, 12
Bleomycin	10 U/m²	IV	Weeks 4, 8, 12
Prednisone	75 mg	Oral	Daily, dose tapered over the last 15 days
Co-trimoxazole	2 tablets	Oral	Twice daily throughout

† MACOP-B = methotrexate with leucovorin rescue, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin; IV = intravenous.

†† Methotrexate given as a 100 mg/m² intravenous bolus, then 300 mg/m² intravenously over 4 hours, followed 24 hours later by folinic acid, 15 mg orally, every 6 hours for 6 doses.

* Klimo P, Connors JM: MACOP-B chemotherapy for the treatment of diffuse large-cell lymphoma. *Ann Intern Med.* 102:596-602, 1985.

Blenoxane*

(sterile bleomycin sulfate)

Brief Summary of Prescribing Information (1) 10/84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane* be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma – Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas – Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma – Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary – This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{CO}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{CO} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{CO} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

(1) Maintain FI O_2 at concentrations approximately that of room air (25%) during surgery and the post-operative period.

(2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions – In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes – These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other – Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban.* It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate. NDC 0015-3010-20

IF IT'S NOT LIQUID IGIV
IT'S NOT AS PURE,
IT'S NOT AS SIMPLE TO USE,
IT'S NOT GAMIMUNE® N

AIDS SAFE*

LIQUID NATIVE IGIV CLEARLY SUPERIOR IN SO MANY WAYS

GREATER IgG PURITY THAN LYOPHILIZED IGIV PRODUCTS

Because its preparation is more complex and better controlled, GAMIMUNE N is a purer form of IgG. Not a trace of porcine pepsin — a potentially antigenic material — exists in the final product.

SIMPLER AND MORE ECONOMICAL TO USE

No reconstitution time. No technician time or sterile equipment required. No potential risk of product contamination prior to administration.

FEWER DOUBTS ABOUT SAFETY

After 40 years of worldwide clinical use, not a single case of viral disease has been associated with Cutter immune globulins. New GAMIMUNE N is prepared by a well-controlled, contamination-free fractionation process that has been proven to eliminate HTLV-III virus. Can any lyophilized IGIV product make this claim?

NEW NATIVE IGIV

GAMIMUNE® N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

PURE AND SIMPLE . . . THE BEST IGIV AVAILABLE

---

*Established by studies in conjunction with the Centers for Disease Control. Data on file, Cutter Laboratories.

Please see following page for brief summary of prescribing information. 86 GAM 1

NEW | NATIVE IGIV

GAMIMUNE® N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 40% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The in vivo half-life of Gamimune N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood; there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION) is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25 – Gamimune® N is 16.5 mEq/L (~0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune N at a dose of 150 mg/kg body weight; following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gamimune N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gamimune N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PL^{A1} alloimmune antibody with platelet anti-PL^{A1} specificity) also responded to treatment with Gamimune N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25 – Gamimune® N should be considered. In patients in whom a response is achieved, the rise of platelets is generally rapid (within 1-5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gamimune N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gamimune N. It is not known whether Gamimune N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune N. Symptoms reported with Gamimune N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25 – Gamimune® N at the infusion site was reported in some cases.

In further studies of Gamimune N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gamimune N for prophylaxis in immunodeficiency syndromes is 100-200 mg/kg (2-4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gamimune N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes; if well tolerated, the rate may be **gradually** increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

Brains, beauty and a great body.

INTRODUCING SYSTEM 8000

8-PARAMETER HEMATOLOGY ANALYZER

So smart, it's a snap to operate.

Hands-off sample preparation and single-button simplicity—that's the essence of the SYSTEM 8000, the "smartest" whole-blood hematology analyzer we've ever built.

Automated dilution, once the exclusive feature of much larger (and more expensive) instruments, is provided with the Series 208™ Dilution system. Your operator simply transfers the dilutions to the automated stage, presses RUN, and the SYSTEM 8000 does the rest. With effortless, 8-parameter performance, this hematology analyzer counts twice, averages, computes final values, displays the results, and provides a printout in less than a minute.

Beautifully built, inside and out.

The beauty of the SYSTEM 8000 is more than skin deep. An extensive self-diagnostics program has been designed to monitor and maint[illegible]igh-tech performance. A printout of c[illegible]cal parameters is provided for troubleshooting purposes. The SYSTEM 8000 automatically performs a self-test—checking electronics, fluidics and reagents, and more in just 45 seconds. And because complete lysis of cell membrane is critical to accurate analysis, the SYSTEM 8000 offers unique built-in lysis detection.

Troubleshooting operation to save you and your patients time and money.

To minimize down time caused by aperture restriction—the primary problem in hematology analyzers—the SYSTEM 8000 features an exclusive self-cleaning mode: our automatic and patented "reverse air-purge/ fluidic flush." Should a clog be detected during a sample run, the two-way cleaning process repeats automatically and a recount is initiated without operator involvement.

The unique design of the SYSTEM 8000 is proven to keep service demands to a minimum, providing highly accurate and reliable hematology analysis. For more information about what the SYSTEM 8000 can do to streamline your operation, write to Baker or call this toll-free number: **1-800-345-3127.**

No one knows more about SYSTEM 8000 — or what it can do for you and your patients.

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to BLOOD. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: BLOOD will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the BLOOD Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in BLOOD represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a $50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to:

John W. Adamson, MD, Editor
BLOOD
University District Building—Room 320
1107 NE 45th St
Seattle, WA 98105

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1986, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $30.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of BLOOD will assume that the authors of research papers published in BLOOD are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and *two* complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least 1/12 inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus*. (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

LEUCOVORIN CALCIUM

LEUCOVORIN CALCIUM INJECTION
Military Depot: NSN 6505-01-054-7008,
50 mg/vial for I.M. use

DESCRIPTION: Each 1 ml ampul of Leucovorin Calcium *Lederle* contains Leucovorin 3 mg as the calcium salt which is the form preferred for intramuscular injection. Preservative: benzyl alcohol 0.9% w/v. The inactive ingredients are sodium chloride 0.56% w/v, Water for Injection qs 100% and sodium hydroxide or hydrochloric acid is used to adjust the pH to approximately 7.7.

Each 50 mg vial of Leucovorin Calcium cryodesiccated powder when reconstituted with 5 ml of sterile diluent contains Leucovorin 10 mg per ml as the calcium salt which is the form preferred for intramuscular injection. Contains no preservative. Dilute only with Bacteriostatic Water for Injection USP which contains benzyl alcohol. The inactive ingredients are sodium chloride 40 mg/vial and sodium hydroxide or hydrochloric acid qs to pH approximately 8.1. When reconstituted as directed, the resulting solution must be used within seven days. If the product is reconstituted with Water for Injection USP, use immediately.

ACTIONS: Leucovorin (folinic acid) is the formyl derivative and active form of folic acid.

Leucovorin Calcium is useful clinically in circumventing the action of folate reductase. There is no evidence that intramuscular doses of greater than 1 mg have greater efficacy than those of 1 mg.

INDICATIONS: Indicated (a) to diminish the toxicity and counteract the effect of inadvertently administered overdosages of folic acid antagonists. (See Warnings) (b) In the treatment of the megaloblastic anemias due to sprue, nutritional deficiency, pregnancy, and infancy when oral therapy is not feasible.

CONTRAINDICATIONS: Not to be administered for the treatment of pernicious anemia or other megaloblastic anemias where Vitamin B_{12} is deficient.

WARNINGS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to lack of Vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

In the treatment of overdosage of folic acid antagonists, Leucovorin must be administered within one hour, if possible, and is usually ineffective if administered after a delay of four hours.

PRECAUTIONS: In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive.

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

DOSAGE: Megaloblastic anemia: No more than or up to 1 mg daily. There is no evidence that intramuscular doses greater than 1 mg daily have greater efficacy than those of 1 mg; additionally loss of folate in the urine becomes roughly logarithmic as the amount administered exceeds 1 mg.

For the treatment of overdosage of folic acid antagonists: To be given in amounts equal to the weight of the antagonist given.

HOW SUPPLIED:

NDC 0205-4004-51—6—1 ml Ampuls
NDC 0205-5330-92—50 mg Vial of Cryodesiccated powder

LEUCOVORIN CALCIUM TABLETS

BRIEF SUMMARY

Before prescribing Leucovorin Calcium Tablets, please consult complete prescribing information.

INDICATIONS AND USAGE: Leucovorin Calcium Tablets are indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (eg, methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS: *General:* Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia, a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin, and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with leucovorin. It is also not known whether leucovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Leucovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when leucovorin is administered to a nursing mother.

Pediatric Use: (See Drug Interactions.)

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m^2 orally or parenterally followed by 10 mg/m^2 orally every six hours for 72 hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the premethotrexate serum creatinine, the leucovorin dosage should be immediately increased to 100 mg/m^2 every three hours until the serum methotrexate level is below 5×10^{-8}M.[7,8] The recommended dosage of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (ie, trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[9,10,11]

Twenty years ago, leukemia* killed enough people to fill the Houston Astrodome.

Twenty years ago, leukemia was a mysterious disease. Little was known about the cause. Less was known about the cure.

But since then, the Leukemia Society of America has funded 32 million dollars of medical research in an all-out effort to find a cure.

Today, more and more people with leukemia are surviving. Living normal lives. But the Leukemia Society won't be satisfied till this killer is stopped for good.

For more information, including the free booklet "What Everyone Should Know About Leukemia," write to: Leukemia Society of America, 733 Third Ave., New York, New York 10017.

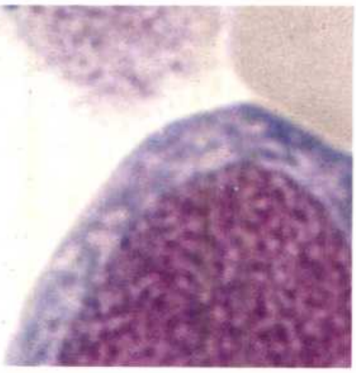
ACCUSTAIN

A new concept in dye technology, brings greater definition and dependability to a host of liquid stains for Hematology and Histology. For example, advanced formulations for Wright Stain and Giemsa Stain are now produced to exacting criteria. Each step of their manufacture is precisely monitored. For total quality control, extinction coefficients are used to verify specific dye component concentrations.

The active ingredients in Wright and Giemsa Stain have been identified as xanthene and thiazine. These components have been isolated, highly purified and combined in exact proportions. This produces a new class of liquid stain formulation, ACCUSTAIN, with unrivaled dye-binding properties.



The new generation of manufacturing technology at Sigma Diagnostics provides Wright Stain and Giemsa Stain with optimal Romanowsky characteristics. These newest members of the ACCUSTAIN family are now available for both manual and automated preparation of blood films.

After many years of waiting, blood cell studies can now be conducted with an unheard degree of precision and Romanowsky definition. The new ACCUSTAIN formulations, Wright Stain and Giemsa Stain offer the hematologist the best vehicles for blood cell examination.

REVIEW

Chromosomal Fragile Sites and Cancer-Specific Rearrangements

By Michelle M. Le Beau

IT IS NOW WELL established that human tumors, particularly leukemias and lymphomas, are characterized by nonrandom chromosomal abnormalities. During the past 2 years, a number of proto-oncogenes and transforming genes have been mapped to the chromosomal breakpoints involved in the specific structural rearrangements. Experimental evidence obtained recently suggests that the genes located at these breakpoints play an integral role in tumorigenesis. Another factor that has added to the interest in cancer-specific chromosomal abnormalities is the recent recognition that the breakpoints noted in the recurring structural rearrangements in human tumors have a remarkable concordance with the location of both heritable and common fragile sites. Moreover, several individuals with malignant diseases characterized by specific abnormalities have been identified as carriers of a fragile site at the point where a chromosome break occurred. Thus, the potential importance of fragile sites relative to genetic predisposition to the development of human tumors is substantial. For this reason, hematologists and oncologists should be aware of research efforts to clarify the role of fragile sites in the pathogenesis of human tumors. Scientific interest in this association is very high, although there are many unresolved issues.

In this review, I will examine the nature and characteristics of the chromosomal fragile sites with an emphasis on those sites that are heritable, the current theories regarding the mechanism(s) of fragile site formation, the correlation of fragile site location with the chromosomal breakpoints in the nonrandom abnormalities noted in human tumors, and the gaps in our current understanding of the role of fragile sites in the pathogenesis of human tumors.

HISTORICAL ASPECTS

The first report of a fragile site was published in 1965 by Dekaban who described a persisting clone of cells with an abnormal C group chromosome in a woman who had received radiation therapy.[1] Three years later, Lejeune et al demonstrated that these sites were heritable when they described a fragile site on the long arm of chromosome 2 in a woman and her daughter.[2] The chromosomal fragile site at Xq27, now known as the fragile X, was first described by Lubs in 1969 in association with mental retardation.[3] In the following years, it became clear that the fragile X chromosome is associated with, if not the cause of, one form of X-linked mental retardation in both males and females.[4]

The heritable chromosomal fragile sites were defined by Sutherland[5,6] as specific points or loci that show the following features: (1) the chromosome has a nonstaining gap of variable width that usually involves both chromatids; (2) the gap involves the same locus in any patient or kindred and is inherited in a Mendelian codominant fashion; (3) the fragility is expressed by the production of acentric fragments, deleted chromosomes, or triradial figures. It has been demonstrated with chromosome polymorphisms that the chromosome expressing the fragile site is always the same homologue. More recently, a second class of fragile sites has been recognized, namely, the common or constitutive fragile sites. The characteristics of this group of fragile sites are described in a later section.

In cytogenetic nomenclature, fragile sites are designated by the triplet "fra" followed by the chromosome number and the chromosome arm and band. For example, the fragile X chromosome may be identified as fra(X)(q27) where q is the long arm and 27 is the band number; p identifies the short arm of the chromosome. The morphologic appearance of one autosomal fragile site, fra(16)(q22), is illustrated in Fig 1.

In the past 10 years, a number of fragile sites have been identified; the key to the detection of these sites was the discovery that fragility may be expressed only under highly specific culture conditions and, in some cases, only in certain tissues. To elicit the expression of fragile sites, Sutherland[7] showed that it was necessary to culture lymphocytes in medium 199 rather than in a variety of other culture media that he examined. The essential feature of medium 199 was later found to be its deficiency in folic acid and thymidine.[5] Since Sutherland's observations, a number of compounds have been identified that can affect the expression of folic acid–sensitive fragile sites. It is well established that the

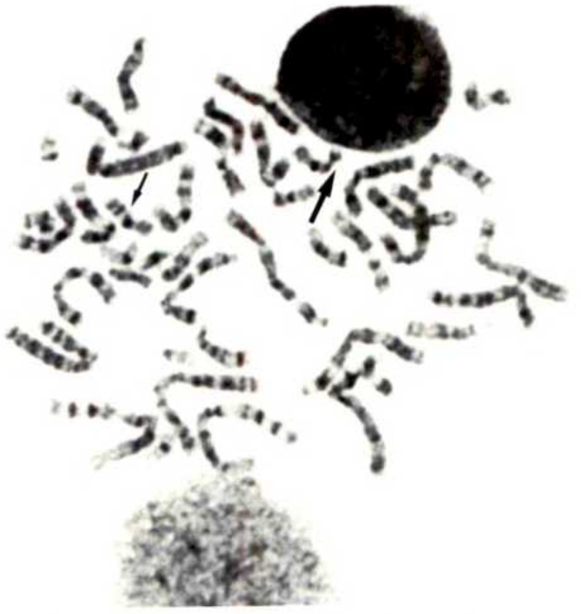

Fig 1. Trypsin-Giemsa banded metaphase cell illustrating the fra(16)(q22) (large arrowhead). A chromosome gap has occurred at band q22 of chromosome 16; the homologous no. 16 is normal (small arrowhead). Phytohemagglutinin-stimulated peripheral blood lymphocytes were cultured in medium 199 (folic acid–free) for 72 hours at 37 °C in a 5% CO_2/95% air atmosphere. Distamycin A (100 μg/mL, Sigma Chemical Co, St Louis) was added for the final 24 hours of incubation; metaphase cells were prepared using standard techniques.

antifolates methotrexate and aminopterin induce this expression,[5] as do the thymidylate synthetase inhibitors fluorodeoxyuridine (FdU), fluorodeoxycytidine (FdC), and trifluorothymidine.[8-10] Conversely, addition of folic acid, folinic acid, thymidine, and bromodeoxyuridine (BrDU) to the medium inhibits expression of the fragile X and folate-sensitive fragile sites in the autosomes.[5]

Several fragile sites are insensitive to the concentration of folic acid in the culture medium; however, each of these can be induced by the addition of certain compounds to the medium. For example, the fra(10)(q25) is expressed only if BrDU is present in the culture medium for at least the final eight to 24 hours.[11,12] The fra(16)(q22) and fra(17)(p12) may be expressed spontaneously in some individuals but are also induced by distamycin A, netropsin, BrDU, bromodeoxycytidine (BrDC), Hoechst 33258, interferon, and caffeine.[13-19]

In addition to the deficiency of folic acid or thymidine or to the presence of other compounds in the culture medium, a number of other factors affecting the expression of fragile sites have been identified. These include the pH of the medium, the duration of the culture, the serum concentration, the presence of methionine, the storage of cells prior to culture initiation, the harvesting technique used, and the method of slide preparation.[4] Because of individual variation and the effects of culture conditions, fragile sites are usually seen in less than 50% of metaphase cells prepared from phytohemagglutinin-stimulated (PHA) peripheral blood lymphocytes. Temporal variations in the percentage of cells expressing heritable fragile sites are commonly observed.

Fragile sites have been studied principally in PHA-stimulated lymphocytes; however, they have also been examined in a number of other tissues. Of the hematopoietic cells, some studies have shown that fragile sites can be expressed in bone marrow cells and in lymphoblastoid cell lines. Other investigations have demonstrated that skin fibroblasts and amniotic fluid cells may be used for the study of fragile sites, although the results have been variable.[19] Finally, expression of the fragile X has also been noted in somatic cell hybrids.[20]

CLASSIFICATION OF FRAGILE SITES

At present, there are 17 recognized heritable fragile sites; 16 of these are autosomal and the 17th is on the X chromosome. The heritable fragile sites can be grouped in three classes based upon the culture conditions necessary for their expression (Table 1).[21,22] Twenty-eight additional fragile sites have been recognized (23 common and five unclassified or possible rare fragile sites), bringing the total number to 45. The first group, that of folate-sensitive fragile sites, comprises 14 of the 17 recognized heritable fragile sites. As described previously, these sites are expressed under tissue culture conditions in which there is a relative deficiency of thymidine. This condition can be achieved by induction with the antifolates methotrexate or aminopterin and by specific inhibition of thymidine synthetase with FdU or FdC.[5,8-10] The folate sensitive fragile sites are 2q11, 2q13, 6p23, 7p11, 8q22, 9p21, 9q32, 10q23, 11q13, 11q23, 12q13, 16p12, 20p11, and Xq27.

The second group, the distamycin A–inducible fragile sites, includes the fra(16)(q22) and the fra(17)(p12). These fragile sites may be expressed spontaneously; however, their expression is enhanced by the presence of distamycin A, interferon, BrDU, netropsin, or Hoechst 33258 in the culture medium.[13-19] The sole member of the third group is the BrDU-requiring fragile site at 10q25, which is expressed only if BrDU is present in the culture medium for at least the final eight to 24 hours of culture.[11,12] The fra(10)(q25) is not induced by the other compounds that induce the group 2 fragile sites.

It is difficult to estimate the frequency of the heritable fragile sites (groups 1 to 3) because in most cytogenetic surveys of newborns and other populations the medium used was not optimal for the expression of fragile sites. However, these fragile sites are generally very rare. The most common is the BrDU-induced site at 10q25, which is present in 2 to 3% of the Australian population.[22,23] Thus, this fragile site can be regarded as a human polymorphism. Estimated frequencies of other fragile sites are 1/200 to 1/700 for the folate-sensitive fragile sites and 1/100 for the fra(16)(q22).[22]

Recently, a fourth group of fragile sites has been described, the common or constitutive fragile sites (Table 1). Our understanding of the nature of these fragile sites is limited; however, they appear to occur in humans with a very high frequency. The common fragile sites may be induced by low folate levels, but expression is enhanced by chemicals such as aphidicolin and caffeine. At the Seventh International Workshop on Human Gene Mapping,[21] three chromosomal regions were classified as common fragile sites,

Includes those fragile sites that were accepted at the Seventh International Workshop on Chromosomes in Leukemia and those listed as common fragile sites in ref 22.

*Expression of group 2 fragile sites is also induced by BrDU, netropsin, Hoechst 33285, and interferon

namely, 3p14, 6q26, and 16q23.[24–28] However, the actual number of common fragile sites may be much higher, as suggested in recent studies by Glover et al[29] who observed breaks at 25 sites induced by aphidicolin, by Yunis and Soreng[30] who described fragility at 51 sites in cells deprived of thymidine and exposed to caffeine, and by Barbi et al[31] who noted 11 folic acid–sensitive sites in cells exposed to methotrexate. The common fragile sites and the chemicals that enhance their expression are reviewed by Sutherland and Hecht.[22]

There are a number of important distinctions between the heritable and the common fragile sites. The heritable fragile sites are rare and segregate in a simple Mendelian fashion with complete penetrance; the common fragile sites, on the other hand, are frequent, if not ubiquitous, and may be caused by environmental factors such as chemicals, radiation, and/or viruses. Moreover, the heritable fragile sites are consistently present in one homologue and are usually manifested as chromosome-type aberrations with chromosome breaks, deletions, and triradials. The common sites may be observed in both homologues, often in the same metaphase cell, and they predominantly consist of chromatid-type lesions. Whether there are additional compounds that enhance the expression of other common sites remains to be determined. Fragility at sites also known to be heritable fragile sites, eg, 8q22 and 16q22, was observed in cells exposed to caffeine or aphidicolin.[29,30] It is unknown whether the heritable fragile sites and the lesions induced by these compounds are identical at the DNA level.

MECHANISMS OF FRAGILE SITE FORMATION

At present, the precise mechanism(s) of fragile site formation is unknown. Initially, it was suggested that these lesions arose simply from despiralization of chromosomes that is mediated by alterations in DNA, histones, nonhistone proteins, or divalent cations.[32] The nature of the inhibitors and inducers of the folate-sensitive fragile sites suggests, however, that the process is likely to operate during DNA synthesis; the common feature of these agents is that they interfere with the 5,10-methylenetetrahydrofolate-requiring conversion of deoxyuridylate to thymidylate. Sutherland[5] proposed that the fragile site is created because a section of thymidine-rich DNA cannot complete synthesis when the thymidine supply is restricted and that the site subsequently does not compact normally during mitosis. It now appears that the actual mechanism may be more complex.

Goulian et al[33] have demonstrated that when the level of thymidine in the medium is low, uracil is misincorporated into DNA during replication. This finding led investigators to propose that the folate-sensitive fragile sites appear as a result of heritable defects of DNA methylation along a chromosome region that normally binds a folding protein involved in chromosome condensation.[34] The misincorporation of uracil in place of thymine into DNA would produce a further loss of methyl groups, eventually precluding a full DNA-folding protein interaction; the result would be a localized collapse of the chromosome structure.

An alternative interpretation of the effects of uracil incorporation into DNA on fragile site formation has also been described.[35,36] The mechanism is based upon the phenomenon of thymidine less death observed in bacteria.[35] The incorporated uracil is subject to recognition and removal by uracil-*N*-glycosylase, and the resulting apyrimidinic sites would be attacked by endonucleases. Each strand break would serve as a site for initiation of an excision-repair patch; in the absence of thymidine, dUMP would be incorporated and removed cyclically, with lengthening of the patches during successive cycles. Ultimately, double-strand breakage would result in fragmentation of the chromosome. Whether the folate-sensitive fragile sites are the consequence of an abortive repair process or of the presence of an altered base remains to be determined.

Additional hypotheses for the formation of fragile sites include that of viral modification of DNA[37] as well as the theory of Lejeune (personal communication, September 1984) that the relative decondensation of chromatin is related to a high rate of transcriptional activity of genes that are specifically induced by folate deprivation. This transcriptional activity would be maintained during early prophase, thereby preventing chromosome condensation. With regard to the former hypothesis that fragile sites represent sites of viral modification of DNA, it is known that infection of permissive cells with adenovirus 12 results in decondensation of three consistent chromosome regions (1p36, 1q21, 17q21). Moreover, Lindgren et al recently mapped to these chromosome regions a multigene family coding for the small nuclear RNA molecules U1 and U2, which have been implicated in RNA processing.[38] They have suggested that the small nuclear RNA genes are the major targets of viral chromosome modification. It is still unknown whether other chromosomal regions such as the fragile sites may also be targets of viral modification.

The relationship of the aforementioned hypotheses to the mechanisms causing the fragile sites inducible by distamycin A and BrDU and to those causing the common fragile sites is unclear. Distamycin A, Hoechst 33258, and netropsin preferentially bind to A-T clusters in DNA and may lead to differential inhibition of chromosome condensation.[39] It may be that BrDU is incorporated into DNA and, like the other three agents, causes conformational changes in the DNA. Moreover, the theory of Lejeune may not be restricted to the folate-sensitive fragile sites in that conformational changes in DNA caused by agents such as distamycin A may also cause alterations in transcriptional activity.

At present, the mechanism by which interferon induces expression of the fra(16)(q22) has not been determined. With regard to the possibility that fragile sites are regions of DNA with a high rate of transcriptional activity, it is of interest that α- and β-interferons induce transcription of the functional metallothionein genes. As described in a later section, the metallothionein genes have been mapped to 16q22; the breakpoint at q22 in the inv(16) and t(16;16) associated with acute myelomonocytic leukemia occurs within the cluster of metallothionein genes, and some of these patients have been found to be carriers of the fragile site at 16q22.

Regarding the common fragile sites, caffeine is believed to induce the synthesis of proteins required for mitosis during the G2 phase, causing cells to enter mitosis before proper repair of lesions in their DNA.[40,41] In experiments on induction of fragile sites by caffeine, cells have been cultured in folate-depleted medium or in the presence of FdU, suggesting that incorporation of uridine into DNA and the subsequent effects of this incorporation may play a role. Aphidicolin, the second chemical known to enhance the expression of the common fragile sites, is an inhibitor of DNA polymerase α and thus may alter the synthesis of DNA in specific chromosome regions.

BIOLOGIC SIGNIFICANCE OF FRAGILE SITES

The association of fragile sites with phenotypic abnormalities is well established for the fra(X), which is associated with one form of X-linked mental retardation that is characterized by macroorchidism and connective tissue dysplasia in affected males. The phenotypic consequences of the autosomal fragile sites are less clear. In general, they are considered to be normal chromosomal variants despite sporadic reports of the presence of fragile sites in individuals who have congenital abnormalities. Recently, fragile sites have been implicated in the pathogenesis of human tumors. In 1983, Yunis found a correlation between three fragile sites and chromosomal rearrangements in malignant cells.[42] Four of five cancer patients studied were found to be carriers of a fragile site in a chromosome region that was also involved in a rearrangement in their malignant cells. Yunis proposed that chromosomal rearrangements might be facilitated by the presence of heritable or constitutional fragile sites.

Le Beau and Rowley[43] identified a remarkable concordance between the chromosomal location of heritable fragile sites and the breakpoints that occur in the nonrandom abnormalities associated with leukemia and lymphoma. This observation was subsequently noted by other investigators.[44,45] Moreover, Hecht and Sutherland[46] determined that there was a statistically significant association between the 21 fragile sites and 50 cancer-specific breakpoints accepted by the Seventh Human Gene Mapping Workshop.[21]

Figure 2 summarizes the location of the 21 fragile sites accepted by the Seventh Human Gene Mapping Workshop as well as the proto-oncogenes and transforming sequences

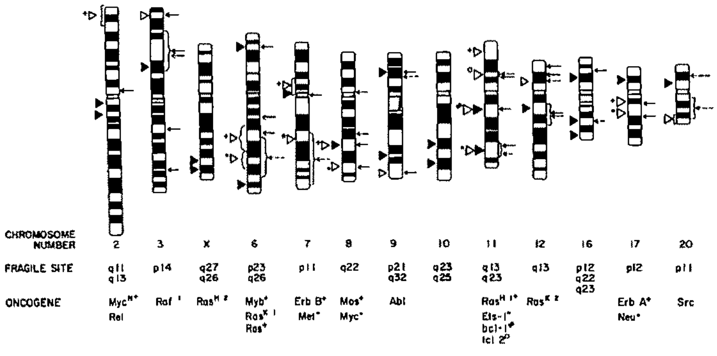

Fig 2. Diagram of chromosomes containing known fragile sites. The chromosome number, fragile site, and proto-oncogene or transforming sequence that has been mapped to these chromosomes are indicated below each chromosome. The arrowheads to the left of each chromosome indicate the bands carrying the fragile site (▶) or proto-oncogene (▷); the arrows to the right of the chromosomes identify specific bands involved in consistent translocations (←) or deletions (←---) that are observed in human tumors. Additional symbols (+, •, #, O) identify the proto-oncogenes or transforming sequence and their location.

that have been mapped to these chromosomes. The nonrandom changes affecting the chromosomes and the malignant diseases in which the karyotypic abnormalities are frequently seen are listed in Table 2. Twenty-four of the nonrandom chromosomal abnormalities observed in leukemia and lymphoma involve eleven regions known to contain heritable fragile sites in some individuals. One additional common fragile site has been localized to a region that is involved in chromosomal rearrangements in solid tumors.

The nonrandom abnormalities in leukemia and lymphoma in which breakpoints coincide with fragile sites are summarized in the following paragraphs. Band p23 of chromosome 6 contains a fragile site and is also the breakpoint in the t(6;9)(p23;q34) which is associated with bone marrow basophilia in ANLL.[47,48] A new recurring translocation, t(1;7)(p11;p11), noted in patients with myeloid disorders (ANLL, MPD, or a MDS) involves a breakpoint at 7p11, which is known to be a fragile site.[49] The t(8;21)(q22;q22)

Abbreviations: BL, Burkitt's lymphoma; ALL, acute lymphoblastic leukemia; NHL, non-Hodgkin's lymphoma; CLL, chronic lymphocytic leukemia; MDS, myelodysplastic syndrome; ANLL, acute nonlymphocytic leukemia; MPD, myeloproliferative disorder; SCLC, small-cell lung carcinoma, ATL, adult T cell leukemia; PLL, prolymphocytic leukemia; AML, acute myeloblastic leukemia; CML, chronic myelogenous leukemia; AMOL, acute monoblastic leukemia; APL, acute promyelocytic leukemia; AMMoL, acute myelomonocytic leukemia.

*Includes only the 21 fragile sites that were accepted at the Seventh International Workshop on Human Gene Mapping[21]

observed in AML with maturation (AML-M2)[50] may be associated with a fragile site that has been identified at 8q22. A fragile site in no. 9 at p21 is also the breakpoint in the t(9;11)(p21 or p22;q23), which has been noted primarily in AMoL.[51] Translocations and deletions involving 9p21 have also been described in patients who had ALL with lymphomatous features.[52] Chromosome 10 contains two fragile sites (10q23,10q25); however, only one of these bands is the breakpoint in a cancer-specific rearrangement. This abnormality, the t(10;14)(q24-25;q11), has recently been observed in patients with ALL or NHL of T cell origin.[53]

There are two fragile sites on no. 11 (q13 and q23), each of which may be the breakpoint in various translocations or deletions in AML and ALL and in lymphoma. These include the t(11;14)(q13;q32) or t(11;14)(q23;q32) in NHL[54] as well as t(9;11)(p21;q23), t(11;19)(q23;p13orq13), ins(10;11)(p11;q23q24), del(11)(q23) and t(11q) in AMoL and AMMoL,[55,56] and t(4;11)(q21;q23) in ALL.[57,58] In no. 16, the fragile site at q22 occurs in the band that is affected in the inv(16)(p13q22), del(16)(q22), and t(16;16)(p13;q22) found in AMMoL characterized by bone marrow eosinophilia and abnormal eosinophil morphology and cytochemical reactions.[59-61] Another fragile site on no. 16, at p12, does not coincide with the short-arm breakpoint in the inv(16) and t(16;16) that has been identified as p13 in prophase chromosomes. Finally, an isodicentric chromosome resulting from a break in the short arm of chromosome 17 has been observed in patients with CML in the acute phase, and in patients with ANLL.[62]

One additional fragile site is located in a chromosomal region that may be rearranged in solid tumors; an interstitial deletion of 3p [del(3)(p14p23)] has been observed in some cell lines derived from patients with SCLC,[63] and translocations involving 3p14 have been noted in familial renal carcinoma [t(3;8)(p14;q24),t(3;11)(p13-14;p15)]. Two chromosome regions, 11q23 and 12p13, are involved in hematopoietic neoplasms as well as in solid tumors; the t(11;22)(q23orq24;q12) has been described in Ewing's sarcoma,[64,65] and translocations and deletions involving 12q13 have been noted in salivary gland tumors.[66]

Thus, 12 of the 21 recognized fragile sites (including 11 of the 17 heritable fragile sites) occur in chromosome bands that are involved in nonrandom abnormalities in human tumors. The association of cancer-specific breakpoints and fragile site locations has been analyzed statistically by Hecht and Sutherland.[46] By using a chi-square test, these authors determined that there was a highly significant statistical association ($P < .001$) between the location of the 21 fragile sites and the 50 recurring cancer breakpoints accepted by the Seventh Human Gene Mapping Workshop.[21]

If a relationship exists between the consistent chromosomal rearrangements in malignant cells and heritable fragile sites, one might expect that those patients whose malignant cells have one of these rearrangements would also be carriers of fragile sites that affect the involved chromosomes. Data from several sources suggest that this may in fact be the case. In 1983, Sessarego et al[67] described the presence of a fra(11)(q13) in peripheral blood lymphocytes of a patient who had myelofibrosis with myeloid metaplasia. An interstitial deletion of 11q [del(11)(q13q21)] with a breakpoint in the same (11q13) band was present in circulating immature cells.

Yunis[42,44] found a correlation between three fragile sites and chromosomal rearrangements in five cancer patients. Two patients with small-cell lymphoma had a t(11;14)(q13;q32) in their malignant cells; in one of these patients, analysis of PHA-stimulated lymphocytes revealed a fragile site at 11q13. A third lymphoma patient who had a t(12;14)(q13;q32) also had a fragile site at 12q13, and both patients studied who had AMMoL and an inversion of chromosome 16, inv(16)(p13q22), carried a fragile site at 16q22. In one of the latter patients, the presence of a heterochromatin variant enabled Yunis to determine that the homologue that was rearranged in the malignant cells also expressed the fragile site. In contrast, of three patients with AMMoL and an inv(16) (two patients) or del(16)(q22) (one patient) studied during complete remission by Arthur and Bloomfield,[68] only one patient was found to have a fragile site at 16q22.

Le Beau and Rowley[43] reported the presence of a fragile site at 16q22 in lymphocytes from four of five patients with AMMoL and an inv(16) who were studied while they were in remission. Chromosome breakage at 16q22 was not observed in any of the five healthy individuals analyzed as controls. We have expanded our studies to include 11 AMMoL patients whose malignant cells were characterized by an abnormality of no. 16 [inv(16), nine patients; del(16), one patient; t(16;16), one patient], and we found that ten of the 11 patients when examined during complete remission were carriers of a fragile site at 16q22. Figure 3 illustrates the inverted chromosome 16 observed in the malignant cells and the fragile site at 16q22 from normal lymphocytes of one of these patients. The parents of one patient with a fra(16) were also examined for the presence of fragile sites. We found that the father was a carrier of a distamycin A–inducible fragile site at 16q22, thereby indicating that, in at least this patient, the fragile site was a heritable site. Arthur et al[69] have also demonstrated the familial nature of the fragile site at 16q22 in a previously reported patient.[68] Specifically, these authors found that the mother and four children of a woman with AMMoL and an inv(16), who also had a fra(16), were also carriers of this fragile site. As mentioned earlier, the estimated frequency of the fra(16)(q22) in the general population is approximately 1/100 individuals; thus, it is unlikely that this fragile site would be observed randomly in ten of 11 patients who have a rearrangement involving 16q22 in their leukemic cells.

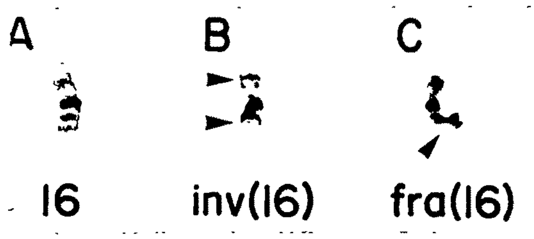

Fig 3. Partial karyotypes of trypsin-Giemsa banded metaphase cells illustrating the (A and B) normal and inverted [inv(16)(p13q22)] chromosome 16 homologues obtained from the malignant bone marrow cells of a patient with acute myelomonocytic leukemia. (C) The fragile 16 [fra(16)(q22)] observed in phytohemagglutinin-stimulated lymphocytes from this patient obtained at the time of complete remission. The chromosomal breakpoints of the inv(16) and the fragile site at 16q22 are identified with arrows.

In addition to the heritable fragile sites, the common fragile sites have recently been implicated as predisposing factors in the development of neoplasia. By culturing cells in the presence of aphidicolin or in folic acid–depleted media supplemented with caffeine or FdU, two groups of investigators have indicated that the number of common fragile sites may be much higher than previously recognized. Moreover, the number of these sites that coincide with chromosomal breakpoints in cancer cells was found to be greater than expected by chance.[29,30,70]

IDENTITY OF GENES LOCATED AT FRAGILE SITES

Although an association of fragile sites and cancer breakpoints has been recognized, the exact nature of the relationship at the DNA or gene level remains obscure. That human malignant diseases are characterized by nonrandom chromosomal abnormalities is now well established. A number of the genes located at the chromosomal break points have been identified, and the direct role of chromosome abnormalities in the pathogenesis of human neoplastic diseases is becoming increasingly evident. In many instances, the genes located at the breakpoints of specific rearrangements were previously recognized as proto-oncogenes; in several other instances, however, previously unknown transforming sequences have been identified. The cellular homologue of the transforming sequence of the Moloney murine sarcoma virus, c-*mos*, has been mapped to 8q22,[71] the breakpoint in the t(8;21) in AML. Another proto-oncogene, c-*ets*-1, has been mapped to 11q23 to q25.[72] This chromosome region is the breakpoint in the t(9;11) in AMoL as well as in the other translocations and deletions associated with this type of leukemia; it is also the breakpoint in the t(4;11) in ALL. Both 8q22 and 11q23 are the location of recognized heritable fragile sites (Fig 2). C-*erbB*, one of the transforming sequences associated with the avian erythroblastosis virus, has been mapped to the proximal region of 7p,[73] which also contains a fragile site as well as a breakpoint in a specific rearrangement, the t(1;7).[49] A transforming gene, *bcl-1*, was identified at the breakpoint on 11q13, which is involved in the t(11;14) in small-cell lymphoma [74] This band also contains a heritable fragile site; several cancer patients with rearrangements involving this band were found to be carriers of this fragile site.[42,67]

In addition to transforming sequences and proto-oncogenes, other genes have been mapped to chromosomal regions that are breakpoints in cancer cells and also are the locations of fragile sites. These genes include the α- and β-interferons (9p21 to p22, t(9;11) in AMoL, del(9p) or t(9p) in ALL).[75,76] In addition, Le Beau et al[77] have mapped the metallothionein family of genes to 16q22 and have shown that this gene cluster is split by the inv(16) and t(16;16) that occur in AMMoL. More importantly, Le Beau and Rowley[43] and Le Beau (unpublished observations, March 1985) have demonstrated that these patients were also carriers of a heritable fragile site at 16q22. With the use of molecular techniques, it will be possible to determine whether the fragile site in these patients also occurs within the metallothionein gene cluster and whether the fragile site involves precisely the same sequences as does the q22 breakpoint of the inv(16) noted in the leukemic cells of these patients. Moreover, it will also be feasible to clone and sequence this fragile site and to determine whether the putative common fragile site at 16q22 occurs at the same point at the DNA level as does the rarer, heritable fragile site.

If fragile sites serve as factors predisposing to chromosomal rearrangements in human neoplasia, one might expect that gene sequences integrally involved in neoplastic transformation would reside at these loci. Unfortunately, our knowledge about the genes located at fragile sites is still limited. In fact, although several genes are mapped to the region of fragile sites, no single gene has been identified at the precise site. The identification and determination of the normal cellular function of the genes located in regions that are both fragile sites and breakpoints in chromosomal rearrangements in malignant cells is an important goal in contemporary cancer research.

UNRESOLVED ISSUES

The reports of an association between the location of fragile sites and chromosomal break points in cancer cells raise a number of questions that have not been answered. Determining the baseline frequency of fragile sites in cancer patients and comparing this frequency to that in the general population is of primary importance. We do not yet know whether patients with cancer who have chromosome rearrangements other than inv(16), t(11;14), del(11q), or t(12;14) are also carriers of fragile sites in the altered chromosome regions. Are these fragile sites the rare heritable or the common fragile sites? Do fragile sites predispose individuals to cancer development? If so, which sites have such an effect, and to what extent? Is such a predisposition limited to the heritable fragile sites? In other words, is the risk associated with the heritable fragile sites different from that associated with the common fragile sites? Does a particular fragile site predispose to a specific type of cancer, and is this predisposition familial? For example, are there families carrying fragile sites in whom the same malignancy that is characterized by the same cytogenetic abnormality has developed in multiple members? If fragile sites are found in unaffected members of the family, how can this be explained? In such an event, can we identify the additional genetic or environmental factors that lead to the development of tumors in only some carriers of fragile sites? Are there additional classes of fragile sites whose expression can be induced? Can fragile sites serve to identify individuals at risk of developing cancer?

A major question is related to the identity of the genes located at fragile sites. Are these the genes that are affected by the chromosomal rearrangements in cancer cells? If so, this would indicate that the genes located at fragile sites are related to malignant transformation. This last question also is pertinent to another issue, namely, do fragile sites act in a specific way, or do they merely provide a mechanism that increases the frequency of breaks? If the gene at the fragile site is identical to the gene that is directly involved in cell transformation, then it will be relatively simple to clarify the association. If, on the other hand, fragile sites act in a relatively nonspecific way, essentially to increase the frequency with which a break occurs in one of two chromosome bands but not within the relevant DNA, then further chromosomal rearrangements must take place that elicit the critical genetic change. In this case, selection will act to favor the particular DNA rearrangement that leads to a proliferative advantage in a specific type of cell. For a proper understanding of this aspect of cellular transformation, it appears critical to determine the identity and the normal cellular function of the genes mapped to regions that are fragile sites as well as breakpoints in cancer cell chromosomes.

At present, the function and identity of genes located at the fragile sites remains an enigma. However, we know that some classes of fragile sites are inherited and that they may therefore be related to a genetic predisposition to the development of malignant diseases. In spite of the many unresolved issues, hematologists and oncologists should be aware of the research in this area because of its importance with regard to genetic susceptibility to cancer. Moreover, the goal of establishing the relationship between fragile sites and cancer breakpoints may enable us to develop means with which to anticipate, prevent, detect, or treat cancer more effectively.

ACKNOWLEDGMENT

I thank Rafael Espinosa III and Diane Roulston for excellent technical assistance, Leslee Snyder for assistance in the preparation of the photographs, Grace Kim for help in the preparation of the manuscript, and Elisabeth Lanzl for editorial assistance. Discussions with Dr Janet D. Rowley have been helpful in the consideration of this problem.

Macrophage Colony Formation Supported by Purified CSF-1 and/or Interleukin 3 in Serum-Free Culture: Evidence for Hierarchical Difference in Macrophage Colony-Forming Cells

By Kenichi Koike, E. Richard Stanley, James N. Ihle, and Makio Ogawa

Using a serum-free culture system, we examined murine macrophage colony formation from bone marrow cells cultured in the presence of purified CSF-1, interleukin 3 (IL 3) or a combination of the two factors. CSF-1 supported macrophage and neutrophil-macrophage colony formation, whereas IL-3 supported the formation of various types of single lineage and multilineage colonies. CSF-1 supported more macrophage colonies from bone marrow cells of normal mice than IL 3, whereas in cultures of bone marrow cells of 5-fluorouracil–treated mice, IL 3 supported more macrophage colonies. A combination of CSF-1 and IL 3 resulted in granulocyte-macrophage (GM) colony formation that was equal to or greater than the sum of GM colony formation supported by the factors individually. The combination of CSF-1 and IL 3 resulted in significant increases in the size of both macrophage and neutrophil-macrophage colonies. Similar increases in colony size were observed when CSF-1 was added to cultures five days after incubation of marrow cells with IL 3. These data support the concept that some of the macrophage colony–forming cells that respond to IL 3 are more primitive than those that are sensitive to CSF-1.

CLONAL CULTURE ASSAYS for hematopoietic cells provide methods for studying functional properties of hematopoietic progenitors. The formation of colonies is supported by growth factors termed colony-stimulating factors (CSFs) that are released by a variety of blood and tissue cells.[1] Some CSFs have been purified to homogeneity and/or molecularly cloned.[2–7] Studies of the purified factors in clonal culture suggest that formation of some types of single-lineage colonies can be supported by more than one factor. For example, CSF-1,[2] GM-CSF,[7] and interleukin 3 (IL 3)[8–11] have been reported to support macrophage colony formation in culture. CSF-1 is relatively specific in stimulation of macrophage colony formation by mouse bone marrow cells,[12] whereas IL 3 supports the formation of a wide variety of single and multilineage colonies.[8–11]

It is generally held that the majority of macrophage colonies in culture are derived from monopotent macrophage progenitors. In analysis of murine paired progenitors, homologous pairs of macrophage colonies were often observed.[13,14] This observation was consistent with the derivation of macrophage colonies from monopotent macrophage progenitors. In the same analysis of paired progenitors, however, we also observed pairs consisting of a macrophage colony and a multilineage colony. This data suggested that committed macrophage progenitors may be derived directly from multipotent progenitors.

It is possible that different CSFs support macrophage progenitors differing in hierarchical stages. In this paper, we wished to delineate further the roles of IL 3 and CSF-1 in macrophage colony formation in culture. To improve the specificity, we established a serum-free culture system and studied macrophage colony formation from marrow cells obtained from normal and 5-fluorourcil (5-FU)-treated mice in the presence of CSF-1 and/or IL 3. 5-FU was used to obtain a population enriched for primitive progenitors. The results suggest that the macrophage colony–forming cells that respond to IL 3 may be more primitive than the macrophage progenitors that are dependent on CSF-1.

MATERIALS AND METHODS

Pure CSF-1 and IL 3. CSF-1 (~8 × 10^7 U/mg protein) was purified to homogeneity from serum-free mouse L cell–conditioned medium as described previously.[2,15] The activity in units per milliliter of CSF-1 preparations was obtained by comparing its activity with a standard preparation in a bone marrow colony assay in agar as described previously.[12] The stock preparation of CSF-1 containing 20,000 U/mL activity was kept frozen in α-medium containing 0 1% crystallized bovine serum albumin (BSA, Sigma Chemical Co, St Louis). IL 3 (~5 × 10^6 U/mg protein) had been purified to homogeneity as previously described.[16] Thymidine incorporation by the IL 3–dependent cell line FDC-P1 was used for the measurement of IL 3 activity [16] The stock solution containing 40,000 U/mL was kept frozen in phosphate-buffered saline containing 1% BSA.

Cell preparation. Ten- to 15-week-old female BDF_1 mice were obtained from Simonsen's Laboratory, Gilroy, Calif. Single-cell suspensions were prepared from pooled femurs of three to five mice. 5-FU (Adria, Laboratories, Inc, Columbus, Ohio) was administered intravenously through the tail vein of the mice at a dose of 150 mg/kg body weight. Bone marrow cells were harvested four days after 5-FU injection.

Clonal cell cultures. Serum-free clonal culture was carried out in 35-mm Lux suspension culture plates (5221R, Flow Laboratories, Inc, Rockville, Md) by using a modification of the technique described by Iscove et al.[17] Unless otherwise specified, culture consisted of 4 × 10^4/mL marrow cells from normal mice or 2 × 10^4/mL marrow cells from 5-FU–treated mice, α-medium (Flow),

1.2% 1,500 cp methylcellulose (Fisher Scientific Co, Norcross, Ga), 1% crystallized globulin-free deionized BSA (Sigma), 10^{-4} mol/L mercaptoethanol (Eastman Organic Chemicals, Rochester, NY), 300 μg/mL fully iron-saturated human transferrin (approximately 98% pure, Sigma), 160 μg/mL soybean lecithin (Sigma), 96 μg/mL cholesterol (Sigma), 10^{-7} mol/L sodium selenite (Sigma), and 200 U/mL IL 3 or 200 U/mL CSF-1. The standard cultures contained 30% fetal bovine serum (Flow) instead of a combination of transferrin, lecithin, cholesterol, and sodium selenite. Plates were incubated at 37 °C in a humidified atmosphere flushed with 5% CO_2 in air.

In situ determination of colony types. In standard experiments, colony types were determined by in situ observation on an inverted microscope. In this case, colony types were classified as to whether they contained granulocyte, macrophage, megakaryocyte, and/or mast cell lineages. GM colonies containing more than 50 cells were scored between days 8 and 14 as indicated in each experiment. Unless otherwise specified, megakaryocyte colonies consisting of more than four cells were scored on day 8 of incubation, granulocyte-macrophage-megakaryocyte (GMM) colonies on day 12 of culture[18] and mast cell colonies and blast cell colonies on day 16 of incubation.[19]

Cytologic examination of colonies. In some experiments, colony types were determined by differential counting of May-Grünwald-Giemsa–stained preparations. We reported previously that the phenotypes of colonies containing blast cells may continue to change as these colonies mature in culture.[18] In serial observations of colony formation from spleen cells of 5-FU–treated mice, we also observed continued appearance of new macrophage and multilineage colonies and their subsequent development throughout the incubation up to 16 days.[20] To determine the full potentials of colonies supported by CSF-1 or IL 3, we carried out cytologic examination of colonies that were harvested from mapping studies. We plated 8 × 10^4 bone marrow cells from normal mice and 4 × 10^4 cells from 5-FU–treated mice in the presence of CSF-1 or IL 3 and carried out daily examination of plates on an inverted microscope. When a new colony appeared, its location in the plate was recorded and subsequent growth and differentiation followed. When a colony appeared to have matured and did not change its morphology or size for three days, it was lifted from the methylcellulose medium by use of an Eppendorf micropipette, and differential counting carried out on May-Grünwald-Giemsa–stained smears. Routinely, differential counts were done on 500 cells. When indicated, colonies were individually lifted by an Eppendorf micropipette, made into single-cell suspensions, and divided into two aliquots. One half of the sample was used for counting in a counting chamber and the other half for analysis of differential counts. Abbreviations used for the description of lineages are modifications of those recommended at a workshop of a UCLA symposium[21]: n, neutrophil; m, macrophage; mast, mast cell; e, eosinophil; E, erythrocyte, M, megakaryocyte.

RESULTS

Colonies supported by CSF-1 or IL 3 in serum-free culture. CSF-1 supported only GM colonies whereas cultures containing IL 3 revealed various types of colonies. GM colony formation seen in serum-free culture in the presence of 200 U/mL CSF-1 or 200 U/mL IL 3 was approximately one half to two thirds of the colony number in the standard culture conditions. An example of such a comparison is presented in Table 1. Although a few colonies were present in serum-containing culture without IL 3 or CSF, there were no colonies in the serum-free plates without added factors. Results of cytologic analyses of all colonies supported by these factors in serum-free culture are presented in Table 2. The majority of the colonies seen in cultures with CSF-1 were small macrophage colonies consisting of less than 400 cells, whereas the remaining one third were neutrophil-macrophage colonies. CSF-1 did not support pure neutrophil colonies. Similar to our previous observations in standard culture conditions,[9-11] IL 3 supported growth of single as well as multilineage colonies revealing varying combinations of lineages in a serum-free system. Macrophage colonies were small and consisted of mature macrophages.

Table 1. GM Colony Formation by Bone Marrow Cells of Normal Mice in Serum-Free or Serum-Containing Cultures

Factor	Serum-Free Culture	Serum-Containing Culture
CSF-1	56 ± 11	111 ± 14
IL 3	58 ± 4	97 ± 7
	(73 ± 6)*	(103 ± 6)
None	0	6 ± 3

*The data presented in parentheses indicate the number of all types of colonies supported by IL 3.

Bone marrow cells in 4 × 10^4 cells/mL were cultured in the presence of 200 U/mL CSF-1 or 200 U/mL IL 3, and colonies were counted on day 8.

Data represent the mean ± SD of quadruplicate cultures.

Next, we carried out a serial examination of colony formation on an inverted microscope to determine the optimal period of culture for neutrophil and/or macrophage colony formation by the purified factors. Since it is not always possible to distinguish accurately among pure macrophage colonies, neutrophil-macrophage colonies, and neutrophil colonies in situ, we combined all three types and reported the total number of GM colonies. Plateaus for the numbers of GM colonies were seen between day 8 and day 11 of incubation for both CSF-1 and IL 3.

Dose response studies. We then examined the effects of various concentrations of CSF-1 and IL 3 on colony formation by normal bone marrow cells. Both factors in serial

dilutions were added to methylcellulose culture of normal bone marrow cells, and the colonies were counted using in situ identification. The results of the dose-response studies are presented in Table 3. Maximal GM colony stimulation was seen at 200 U/mL of CSF-1 or IL 3. Based on these studies, the standard concentrations for CSF-1 and IL 3 became 200 U/mL.

Effects of combination of CSF-1 and IL 3. Results presented in Tables 1 to 3 clearly demonstrate that macrophage colony formation is supported by both CSF-1 and IL 3. In addition, multilineage colony formation was supported by IL 3, as was documented previously.[9-11] The latter information suggests that the targets of IL 3 include primitive progenitors. To better define the roles of CSF-1 and IL 3, we cultured marrow cells in the presence of CSF-1 or IL 3 and the combination of CSF-1 and IL 3 and examined the number, types, and sizes of GM colonies.

First, we cultured 3 × 10^4 marrow cells of normal mice and 2 × 10^4 marrow cells of 5-FU–treated mice in quadruplicate cultures and analyzed GM colonies on days 8, 11, and 14 of incubation (Table 4). The number of GM colonies supported by a combination of CSF-1 and IL 3 were close to or in excess of the sum of the number of colonies supported by CSF-1 and IL 3 separately. This information suggests that the GM colony–forming cells that are targets of CSF-1 and IL 3 are not identical. They could represent basically separate populations without significant overlap. Alternatively, there may be populations of GM progenitors that require both CSF-1 and IL 3 for their proliferation.

In addition to the increase in the number of colonies, the combination of CSF-1 and IL 3 resulted in a significant enlargement of GM colonies. In a separate experiment, 20 macrophage and 20 neutrophil-macrophage colonies were individually picked from each group and analyzed for their cell number and composition. The size distribution of these colonies is presented in Fig 1 on a logarithmic scale. For both macrophage and neutrophil-macrophage colonies, the populations grown in the presence of both CSF-1 and IL 3 were significantly larger than colonies grown either in CSF-1 or IL 3 alone. Addition of CSF-1 did not increase the size of neutrophil colonies supported by IL 3 (data not shown).

Delayed addition of factors. The aforementioned data suggested that one of the two factors promoted the growth of the colonies initiated by the other factor. IL 3 is known to exert its effects on primitive multipotent progenitors. Therefore, we entertained the possibility that CSF-1 promoted the development of IL 3–initiated macrophage colonies. To test this premise, we carried out delayed addition experiments. In group A, bone marrow cells from normal mice were plated in the presence of 200 U/mL IL 3. Five days later, either 200 units of CSF-1 or α-medium was layered over each dish, and culture was continued. Six days later, all GM colonies were scored in situ and individually picked for simultaneous cytologic examination and estimation of colony size. The mean and one SD of the numbers of GM colonies derived from 3 × 10^4 cells were 59 ± 1 and 46 ± 6 for CSF-1 and α-medium groups, respectively. These numbers were significantly different ($P < .05$) according to Student's t test and suggested the presence of GM progenitors that require both CSF-1 and IL 3 for continued proliferation in culture.

The delayed addition of CSF-1 not only increased the number of GM colonies but also resulted in a significant enlargement of some of the GM colonies. Analysis of colony size of 20 randomly chosen macrophage colonies and neutrophil-macrophage colonies in the two experimental groups is presented in Fig 2A. Both macrophage colonies and neutro-

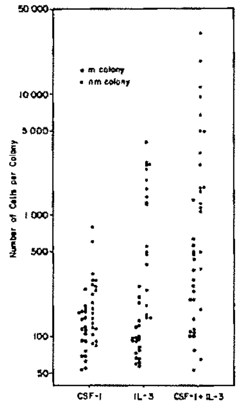

Fig 1. Distributions of sizes of 20 randomly chosen macrophage (m) colonies and 20 neutrophil-macrophage (nm) colonies cultured in the presence of CSF-1 or IL 3 or a combination of CSF-1 and IL 3. Macrophage colonies in the CSF-1 + IL 3 group were larger than those in the CSF-1 group ($P < .01$) and the IL 3 group ($P < .01$). Neutrophil-macrophage colonies in the CSF-1 + IL 3 group were larger than those in the CSF-1 group ($P < .001$) and the IL 3 group ($P < .02$). Statistical analyses were done using Student's *t* test on logarithms of the cell numbers.

phil-macrophage colonies in the CSF-1 group were significantly larger than colonies in the α-medium group. The increase in the size of neutrophil-macrophage colonies was due to an increase in the macrophage population ($P < .001$ by *t* test on logarithms of the cell number) but was not due to an increase in neutrophils ($P > .1$). The data for the CSF-1 group in Fig 2A are similar to the data for the group with a combination of IL 3 and CSF-1 in Fig 1, suggesting that CSF-1 promotes cell proliferation during later stages of macrophage colony development that had been initiated by IL 3.

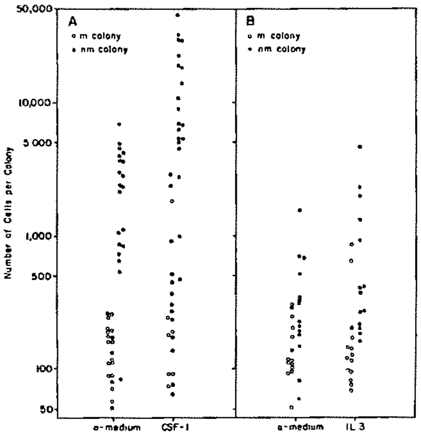

Fig 2. Distributions of sizes of macrophage colonies (m) and neutrophil-macrophage (nm) colonies seen in the delayed addition experiment. (A) Cultures were initiated with IL 3 on day 0. CSF-1 or α-medium was added on day 5. Both macrophage colonies and neutrophil-macrophage colonies in cultures receiving CSF-1 on day 5 of incubation were larger than their counterparts in the control (α-medium) group, $P < .02$ and $P < .001$, respectively ($n = 20$). (B) Cultures of bone marrow cells were initiated with 200 U/mL of CSF-1 and received 200 units of IL 3 or α-medium on day 5. There was no significant difference in the size of colonies between experimental (IL 3) and control (α-medium) groups ($n = 14$). Student's *t* test was applied to logarithms of the cell numbers as was in Fig 1.

Cultures in group B received the factors in reverse order. Bone marrow cells were plated in the presence of 200 U/mL CSF-1 and five days later received either 200 units of IL 3 or α-medium. When colonies were counted six days thereafter, the mean and one SD of the number of GM colonies from 3×10^4 marrow cells were 28 ± 5 and 22 ± 4 for the IL 3 and α-medium groups, respectively, and did not show significant differences ($P > .1$ by the *t* test). The size of GM colonies did not differ significantly between the experimental and control groups. Analysis of colony size of 14 randomly picked macrophage colonies and neutrophil-macrophage colonies is presented in Fig 2B. Colonies in both groups were relatively small, and none reached the size of the large colonies shown in Figs 1 and 2A.

Effects of CSF-1 and IL 3 on colony formation from bone marrow cells of 5-FU–treated mice. Data presented in Fig 2 suggested that the macrophage colony–forming cells that responded to CSF-1 are maturer than those that are targets for IL 3. Additional support for the heterogeneity of macrophage CFU was derived from studies of colony formation from bone marrow cells of 5-FU–treated mice. As originally described by Hodgson and Bradley[22] and subsequently in our laboratory,[20] an intravenous injection of 150 mg/kg of 5-FU into mice selectively kills cells that have active DNA synthesis while sparing dormant primitive hematopoietic stem cells. We cultured bone marrow cells of 5-FU–treated mice in the presence of CSF-1 or IL 3. Table 5 presents the cytologic examination of all colonies that were sequentially identified in plates containing either CSF-1 or IL 3. Only three small macrophage colonies and no neutrophil-macrophage colonies were seen in plates containing CSF-1. In contrast, during 16 days of incubation, a total of nine macrophage colonies and 23 neutrophil-macrophage colonies were observed in plates containing IL 3. Therefore, the number of macrophage and neutrophil-macrophage colonies supported by CSF-1 in

post–5-FU marrow cells was significantly smaller than that of those supported by IL 3. This result markedly contrasted the result of culture of normal marrow cells presented in Table 2 and provided additional evidence that IL 3–dependent macrophage proliferation represents an earlier stage of differentiation than the CSF-1–dependent process.

DISCUSSION

As previously indicated, the development of single-lineage colonies may be supported by more than one factor. Bradley and his associates[22-24] identified a primitive macrophage progenitor termed HPP-CFC and proposed that the development of large macrophage colonies from HPP-CFC requires both CSF-1 and a factor(s) with synergistic activity. The synergistic activity is present in media conditioned by human spleens and placenta or the supernatant of cultures of the murine myelomonocytic leukemia cell line WEHI-3. Iscove et al[25] also observed synergistic activity in support of macrophage colony formation by partially purified WEHI-3 burst-promoting activity (BPA) and CSF-1. Although the synergistic activity of WEHI-3 is likely to be due to IL 3,[26] the synergistic activity in human preparations has different properties.[27]

In this paper, we addressed the mechanisms of synergism between CSF-1 and IL 3 on macrophage colony formation in culture. Since fetal bovine serum is potentially an endogenous source of various types of CSF, we carried out studies in a serum-free culture system. Although this system is not chemically defined, it provided a system in which macrophage colony formation was totally dependent on added growth factors. Using purified preparations of CSF-1 and IL 3, we have shown that CSF-1 supports more macrophage colonies from bone marrow cells of normal mice than IL 3, whereas in cultures of bone marrow cells of 5-FU–treated mice, IL 3 supported more macrophage colonies. A significant increase in the size of macrophage colonies and neutrophil-macrophage colonies was observed when CSF-1 was added to cultures five days after incubation of marrow cells with IL 3. The increase in the size of neutrophil-macrophage colonies was due to an increase in the macrophage population. These data suggested the heterogeneity in macrophage colony–forming cells that respond to IL 3 and CSF-1 and provided further clarification of the synergistic mechanisms between CSF-1 and IL 3 on macrophage colony formation.

Studies of the action of CSF-1 and IL 3 in suspension cultures also indicated that IL 3 acts on more primitive progenitors than CSF-1.[28] In cultures enriched for very primitive cells (bone marrow cells harvested one day after injection of 5-FU), IL 3 increased the number of nonadherent CSF-1 binding cells whereas CSF-1 did not. In cultures containing more mature cells (marrow cells harvested six days after 5-FU injection), CSF-1 generated approximately 17 times more adherent CSF-binding cells than partially purified IL 3. In addition, the effects of IL 3 plus CSF-1 on the very primitive cells were shown to be slightly synergistic. These observations on CSF-1–binding cells in suspension culture corroborate our current studies on macrophage colony–forming cells and indicate the heterogeneity in macrophage progenitors that are responsive to CSF-1 and IL 3.

Mechanisms of some of the observations made in the current studies are unclear. Purified CSF-1 supported the formation of macrophage colonies and neutrophil-macrophage colonies, but not pure neutrophil colonies. We observed a few neutrophil colonies supported by CSF-1 in serum-containing culture (data not shown). Using a standard culture system containing serum and a different strain of mice, we have observed no neutrophil colony production by CSF.[29] Metcalf and Burgess[30] observed the presence of small numbers (2%) of neutrophil colonies. Differentiation of neutrophils requires neutrophil specific factor(s)[31] Small amounts of such factor(s) may be present in fetal bovine serum and may be released by macrophages in the neutrophil-macrophage colonies. Purified IL 3 supported the formation of single-lineage neutrophil, macrophage, mast cell, and megakaryocyte colonies. The majority of the cells in these colonies are mature cells with distinct cytoplasmic differentiation.

In our previous publication,[11] we presented evidence that IL 3 provides a permissive milieu for the growth of multipotential progenitors that begin active proliferation after varying periods of G_0. We have also shown that cells that are committed to single-lineage differentiation may be derived directly from multipotential progenitors by a stochastic process.[13] It appears that the stochastic process of commitment to single lineages is supported by IL 3. As these progenitors mature, they appear to develop sensitivity to more lineage-restricted factors such as CSF-1. In the case of CSF-1, the development of sensitivity is correlated to an increase in the expression of CSF-1 receptors.[28]

ACKNOWLEDGMENT

We would like to thank Lobelia A. Avila and Geneva Winkler for their excellent technical assistance, Dr Pamela N. Pharr for her advice on the manuscript, and P. Linda Skipper for assistance in the preparation of this manuscript.

Myeloperoxidase Biosynthesis by a Human Promyelocytic Leukemia Cell Line: Insight Into Myeloperoxidase Deficiency

By William M. Nauseef

The biosynthesis and processing of myeloperoxidase (MPO), a cationic enzyme present in the azurophilic granules of human polymorphonuclear leukocytes (PMNs), were studied in the human promyelocytic leukemia cell line, HL-60. HL-60 cells produce large quantities of enzymatically active MPO that has the same electrophoretic behavior as MPO isolated from normal PMNs. Mature MPO is a glycoprotein of approximately 150,000 molecular weight (mol wt) composed of two heavy-light protomers ($\alpha_2\beta_2$) with subunits of 59,000 and 13,500 mol wt, respectively, under reducing conditions. The primary translation product of MPO messenger RNA (mRNA) isolated from HL-60 cells was a single polypeptide of mol wt 80,000. In HL-60 cells labeled with [^{35}S]-methionine, the labeled MPO isolated by immunoprecipitation had a mol wt of 89,000. Treatment of this 89-kilodalton (kDa) species with endoglycosidase H produced a 79-kDa peptide, suggesting that the 89-kDa protein contained high-mannose side chains. The 89-kDa species had no detectable peroxidase activity. During chase experiments some of the 89-kDa peptide was processed to smaller species of mol wt 39,000, 59,000, and 13,500, although a fraction of the 89-kDa peptide remained unprocessed after a chase of 100 hours. In addition, a small amount of the 89-kDa peptide appeared in the medium without any of the processed smaller peptides. These studies suggest (1) that the primary translation product in MPO biosynthesis is an 80-kDa peptide that undergoes cotranslational cleavage of the signal peptide and glycosylation to produce an 89-kDa pro-MPO, (2) that pro-MPO is a single polypeptide containing the α and β subunits of MPO and contains endoglycosidase H–susceptible high-mannose side chains, and (3) that posttranslational modification of pro-MPO results in targeting to the lysosome and proteolytic maturation of pro-MPO to active enzyme. In light of the previous observation that MPO-deficient and normal PMNs contain an 89-kDa protein immunochemically related to MPO, these studies on MPO biosynthesis indirectly support the hypothesis that defective posttranslation processing by pro-MPO may underlie hereditary MPO deficiency.

© 1986 by Grune & Stratton, Inc.

MYELOPEROXIDASE (MPO),[1] a cationic glycoprotein present in the azurophilic granules of human polymorphonuclear leukocytes (PMNs), plays an important role in PMN microbicidal activity.[1] Numerous investigators have characterized the function of MPO in oxygen-dependent events following PMN stimulation. The structure of MPO has likewise been extensively studied,[2] and although some disagreement exists, most studies suggest that MPO is composed of a pair of identical heavy-light protomers with a combined mol wt of approximately 140 to 150,000.[3-9] The two protomers are each composed of a 59-kDa α subunit and a 13.5-kDa β subunit and are linked along their long axis by a single disulfide bond joining the two heavy[5] or two light[6] subunits. MPO contains 2% to 4% carbohydrate,[6,10] and a recent study of the subunit structure indicates that the 59-kDa subunit is glycosylated, whereas the 13.5-kDa subunit has no carbohydrate.[11]

Hereditary MPO deficiency has been identified as a relatively common defect, present in one of 2,000 individuals in the population.[12] Although initial studies suggested that MPO deficiency is the result of a structural gene defect inherited as an autosomal recessive trait,[13-18] recent family studies suggest that the mode of inheritance is more complex.[12] In vitro studies of PMN function from such individuals demonstrate delayed bactericidal[12,13,19-21] and an absence of candidacidal action.[12-14,22] PMNs from individuals with functional MPO deficiency do not contain normal subunits of MPO, as determined by polyacrylamide gel electrophoresis (PAGE) and immunoblotting.[3] However, both MPO-deficient and normal PMNs contain an 89-kDa peptide that is immunochemically related to MPO.[3] The presence of this large peptide immunochemically related to MPO in both MPO-deficient and normal PMNs suggests that MPO deficiency may be due to defective processing of an MPO precursor, which results in aberrant packaging of MPO into the azurophilic granules. The goals of this work are to characterize the events in MPO synthesis and to determine the steps that are critical for correct transfer of nascent MPO from its intracellular site of synthesis to its final intracellular destination in the azurophilic granule. With these results it will be possible to examine the nature of the defect in hereditary MPO deficiency.

For these studies the human promyelocytic leukemia cell line HL-60[23,24] was used to examine MPO synthesis because PMNs are terminally differentiated cells with little, if any, protein synthesis.[25] Undifferentiated HL-60 cells produce 47.5 μg of MPO per 10^7 cells,[26] and the MPO produced has a normal subunit structure as determined by immunoblot analysis.[27] This cell line thus provides a useful system for the study of MPO synthesis. Data presented here are consistent with the hypothesis that MPO deficiency is due not to the absence of the gene for MPO synthesis but to a defect in

cotranslational or posttranslational processing of the precursor protein of MPO, resulting in a failure to package the enzyme correctly into the azurophilic granule.

MATERIALS AND METHODS

Reagents. Diisopropylfluorophosphate (DFP), leupeptin, pepstatin A, phenylmethylsulfonylfluoride (PMSF), cetyltrimethylammonium bromide (CETAB), Triton X-100, EDTA, and molecular weight markers for polyacrylamide gels were obtained from Sigma Chemical Co (St Louis) Suspensions of formalin-fixed *Staphylococcus aureus* (Cowan strain) were used as a source of protein A in immunoprecipitation and were obtained from Bethesda Research Laboratories (Gaithersburg, Md). Cowan cells were heated to 95 °C for 30 minutes in 10% 2-mercaptoethanol and 3% sodium dodecyl sulfate (SDS) as previously described[28] and stored as 10% suspensions in phosphate-buffered saline at −20 °C until use. Immediately prior to use, the 10% suspension of Cowan cells was washed sequentially with 1-mL volumes of 0.5% Triton X-100 (Tx-100) in 10 mmol/L Tris buffer, pH 7.5, with 150 mmol/L NaCl (TBS), 2 mol/L urea in .5% Tx-100 in TBS, 1 mg/mL bovine serum albumin in 0.5% Tx-100 in TBS, and TBS before reconstitution to 10% suspension in TBS. RPMI 1640 Select Amine Kit (GIBCO, Grand Island, NY) was used to prepare the methionine-free medium that was supplemented with 1 mmol/L pyruvate and 10% heat-inactivated fetal calf serum (FCS) supplied by the Tissue Culture Facility of the Cancer Center at the University of Iowa. [^{35}S]-methionine of high specific activity (1,495 Ci/mmol) was purchased from Amersham Corp (Arlington Heights, Ill). Endoglycosidase H was obtained from Dr Frank Maley (Albany, NY). Micrococcal nuclease (15,000 U/mL) was obtained from Worthington Biochemical Corp (Freehold, NJ)

HL-60 cells. The human promyelocytic cell line HL-60 was obtained from Dr Harry L. Malech of Yale University and grown in RPMI 1640 medium supplemented with 1 mmol/L pyruvate and 10% heat-inactivated FCS.

Polyacrylamide gel electrophoresis Samples were solubilized in gel sample buffer and placed in a boiling water bath for two minutes. Bromophenol blue tracking dye in 50% glycerol was added to samples prior to electrophoresis. Electrophoresis of samples from labeling experiments or in vitro translations was performed in 0.7-mm-thick gradient gels of 8% to 14% acrylamide and 0% to 14% glycerol with a stacking gel of 3.5% acrylamide. Gels were electrophoresed overnight at 40 V (constant voltage), and the voltage was increased the following morning until the dye front migrated 10.5 cm into the gel. The gel was then stained for protein with R-250 Coomassie blue in 50% methanol and 10% acetic acid and destained in 15% methanol/10% acetic acid. For fluorography the gel was soaked in 400 mL (20 vol) water for 30 minutes and 200 mL (10 vol) of 1 mol/L salicylate (pH 5.7) for 30 minutes as described by Chamberlain.[29] Gels were dried and exposed to preflashed X-Omatic XAR-5 film (Kodak, Rochester, NY) and kept at −80 °C until the autoradiograph was developed. Molecular weights were calculated from plots of R_f v log M_r, using myosin (205 kDa), β-galactosidase (116 kDa), phosphorylase B (97.4 kDa), bovine serum albumin (BSA, 66 kDa), ovalbumin (45 kDa), and carbonic anhydrase (29 kDa) as standards.

Immunoautoradiography. Samples were electrophoresed into 10% polyacrylamide gels prior to electroblotting to nitrocellulose paper according to the method of Towbin et al[30] and processed as described previously [3] The nitrocellulose paper to which proteins had been transferred was exposed sequentially to 3% BSA in Burridge buffer (50 mmol/L Tris-HCl, 150 mmol/L NaCl, .005% NaN$_3$, pH 7.4), anti-MPO antiserum diluted 1:40 in 3% BSA–Burridge buffer, and [^{125}I]-protein A (200,000 cpm/mL) in 3% BSA–Burridge buffer. After multiple washes in Burridge buffer, the paper was dried and exposed to X-Omatic film in a casette with an intensifying screen.

Preparation of RNA Total cellular RNA was prepared by the method of Chirgwin et al[31] from pellets of HL-60 cells harvested from cultures in suspension. The total RNA obtained, estimated by the absorbance at 260 nm (A_{260} = 1 for 42 μg/mL), was 3.05 μg per 10^6 cells Later experiments using a phenol-chloroform extraction of HL-60 cell pellets gave qualitatively the same results but a higher yield of biologically functional RNA as judged by in vitro translation.

In vitro protein synthesis The RNA isolated from HL-60 cells was translated in vitro according to the method of Hunt and Jackson[32] using a rabbit reticulocyte-lysate system and [^{35}S]-methionine. Lysates of rabbit reticulocytes were prepared in the laboratory of Dr Edward C. Heath, Department of Biochemistry, University of Iowa. Lysates were prepared without addition of exogenous methionine and treated with micrococcal nuclease[33] to inhibit translation of endogenous RNA and to increase dependence of translation on exogenously added RNA. Typical translations were done in a volume of 55 μL and contained 5 to 15 μg of total RNA and 85 to 100 μCi of [^{35}S] methionine. In all experiments translation mixtures to which no RNA was added served as controls.

Precipitations Protein was precipitated from 10% trichloroacetic acid and counted to estimate the total amount of [^{35}S]-methionine incorporated into protein. Immunoprecipitations were carried out in two steps: the first to remove any labeled proteins that nonspecifically bind to rabbit serum or to Cowan cells and the second to precipitate specifically labeled protein related to MPO. Samples were diluted in a microfuge tube to 150 μL with TBS, 7 μL of nonimmune rabbit serum was added, and the sample was incubated at 4 °C for 30 minutes. Cowan cells (100 μL of a washed 10% suspension) were added and the sample vortexed and incubated at 4 °C for 30 minutes Cowan cells were removed by centrifugation (12,000 g for one minute) and the supernatant fluid (approx 230 μl) transferred to another 1.5-mL microfuge tube The sample was brought to 2% SDS by the addition of 35.4 μL of 15% SDS, placed in a boiling water bath for two minutes, and then diluted with 1.06 mL (4 vol) of dilution buffer (50 mmol/L Tris-HCl 190 mmol/L NaCl, 2.5% Tx-100, 6 mmol/L EDTA, pH 7.4). The sample was vortexed, 5 μL of rabbit anti-MPO antiserum prepared as described previously[3] added, and the sample incubated at 4 °C for five to 16 hours Cowan cells (100 μL of a 10% suspension) were added and the sample incubated at 4 °C for 30 minutes The suspension was layered atop a 400-μL cushion of 1 mol/L sucrose in TBS and centrifuged (12,000 g for five minutes in a Beckman Microfuge 12) to pellet the Cowan cells The supernatant fluid was aspirated and discarded and the pellet washed sequentially with 1 mL of 0.5% Tx-100/TBS, 2 mol/L urea in 0.5% Tx-100/TBS, 1 mg/mL BSA in 0.5% Tx-100/TBS, and TBS. After the final wash the pellet was resuspended in 100 μL of gel sample buffer (62.5 mmol/L Tris HCl, 190 mmol/L NaCl, 6 mmol/L EDTA, 2.3% SDS, 2.5% Tx-100, 5% 2-mercaptoethanol, pH 6.8), heated for two minutes in a boiling water bath to release the antigen-antibody complex from the protein A on the Cowan cells, vortexed while hot, and centrifuged to remove Cowan cells A 20-μL aliquot of the supernatant fluid was solubilized in 200 μL Scintigest (Fisher Chemical Co, St Louis) and 2.5 mL of scintillation fluid (19 g 2,5-diphenyloxazole, 439 mg dimethyl-2,5-diphenyloxazole, 1,165 mL Tx-100 in 2,330 mL toluene) to count activity of [^{35}S]. The remainder of the sample was electrophoresed into an SDS polyacrylamide gel.

Separation of subcellular components. HL-60 cells were harvested, washed, and resuspended in 20 mL of relaxation buffer (100 mmol/L KCl, 3 mmol/L NaCl, 1 mmol/L adenosine triphosphate (ATP) (Na)$_2$, 3.5 mmol/L MgCl$_2$, 10 mmol/L piperazine-N,N^1-bis

(2-ethanesulfonic acid) (PIPES), pH 7.3, containing 1 mmol/L DFP for 30 minutes on ice as described previously for PMNs.[34] The cells were centrifuged (1400 g for ten minutes) and resuspended in the same buffer without DFP. The subcellular fractions were obtained by nitrogen cavitation separated on a discontinuous gradient of Percoll according to the technique of Borregaard et al.[34] Fractions (1.0 mL) were collected and Percoll removed by ultracentrifugation (180,000 g for 120 minutes) prior to further analysis.

Biochemical analysis. Fractions from the Percoll gradient were assayed for biochemical markers of subcellular organelles. Alkaline phosphatase (plasma membrane) activity was assayed in a 1-mmol/L $MgCl_2$, 50-mmol/L sodium barbital buffer (pH 10.5) as the hydrolysis of *p*-nitrophenyl phosphate (1 mg/mL).[35] Lysozyme (granules) was assayed spectrophotometrically at 450 nm as the disappearance of turbidity of 0.2 mg/mL of *Micrococcus lysodeikticus* in 67 mmol/L sodium phosphate buffer at pH 6.2[36] Myeloperoxidase activity was determined by the oxidation of *o*-dianisidine.[37] Galactosyl transferase (Golgi) was measured as described by Beaufay et al[38] and modified by Brown and Swank.[39]

Biosynthetic labeling. HL-60 cells were harvested by centrifugation and resuspended at 3×10^6/mL in a methionine-free RPMI 1640 medium with 1 mmol/L pyruvate and 10% heat-inactivated FCS that had been dialyzed against phosphate-buffered saline (pH 7.4) in 6,000-mol wt cut-off dialysis tubing prior to addition to the RPMI. Cells were incubated for 30 minutes at 37 °C in an atmosphere of 5% CO_2 in methionine-free medium prior to addition of $[^{35}S]$-methionine (100 μCi/mL). In pulse-chase experiments an excess of unlabeled methionine (1 mmol/L) was added at the end of the labeling interval, and incubation was continued for the designated period of time. At the end of the incubation, cells were recovered by centrifugation (1,400 g for ten minutes). Cell pellets were solubilized in phosphate-buffered (10 mmol/L potassium phosphate, 150 mmol/L NaCl at pH 7.0) saline with 10 mmol/L EDTA, 1 mmol/L PMSF, 100 μg/mL leupeptin, 100 μg/mL pepstatin A, 0.5% CETAB, and 0.1% Tx-100 on ice for 30 minutes. The solubilized cells were clarified by ultracentrifugation (100,000 g for 60 minutes in a type 50 Ti Beckman rotor [Beckman Instruments, Fullerton, Calif]) and the supernatant fluid frozen at −80 °C or subjected to analysis immediately.

Endoglycosidase H treatment. Antigen-antibody complexes were released from Cowan cells by adding 50 μL of 0.2% SDS and 5% 2-mercaptoethanol and heating the suspension in a boiling water bath for two minutes. Free Cowan cells were removed by centrifugation (12,000 g for one minute) and the supernatant diluted to 500 μL with 150 mmol/L citrate buffer (pH 5.5) to reduce the concentration of SDS to .02%. Five microliters of 100 mmol/L PMSF was added to inhibit proteolysis during the deglycosylation. A quantity of 50 ImU of endoglycosidase H (endo H) was added and the sample incubated at 37 °C for 24 hours with constant agitation. As control, 50 μL of citrate buffer was added to an identical sample. At the end of the incubation period, 50 μL of 100% trichloroacetic acid (TCA) was added and the sample placed on ice for 30 minutes. The resultant precipitate was washed twice in 500 μL of 50% methanol and then dissolved in 100 μL of gel sample buffer, heated in a boiling water bath for two minutes, and electrophoresed as will be described.

RESULTS

Use of HL-60 cell line. Because PMNs isolated from venous blood synthesize little or no protein,[25] it was necessary to use the HL-60 cell line to analyze MPO biosynthesis. To verify that HL-60 cells were appropriate for these studies, the MPO subunits synthesized by HL-60 cells were studied by immunoblotting. MPO purified from human PMNs as previously described,[3] normal PMNs, and HL-60 cells were electrophoresed into a 10% polyacrylamide gel under reducing conditions, followed by electroblotting of separated proteins to nitrocellulose paper. Autoradiography of the resulting immunoblot (Fig 1) demonstrated that purified MPO (lane 1), HL-60 cells (lane 2), and normal PMNs (lane 3) contain the same MPO subunit peptides of 59 kDa (α subunit) and 13.5 kDa (β subunit). In addition, the anti-MPO antiserum also identified an 89-kDa peptide present in HL-60 cells and normal PMNs. When the antiserum was adsorbed with purified MPO prior to treatment of the nitrocellulose paper, this 89-kDa peptide as well as the normal subunits of MPO were no longer detected (data not shown). These observations indicate that the 89-kDa species is immunochemically related to normal MPO and that HL-60 cells provide a suitable model to study MPO biosynthesis.

In vitro translation. To identify the primary translation product of MPO mRNA, RNA isolated from HL-60 cells was translated in a micrococcal nuclease-treated rabbit reticulocyte lysate system and the products immunoprecipitated. The primary translation product was an 80-kDa peptide (Fig 2) that represented 0.16% of the total TCA-precipitable counts when translation was performed for 60 minutes. The addition of 3% polyethylene glycol or 50% $(NH_4)_2SO_4$ to the supernatant remaining after the immunoprecipitation failed to recover additional MPO-related peptides. This finding confirms recent reports of the primary translation product of MPO mRNA from HL-60 cells.[40-42] This result demonstrates that the nonglycosylated peptide backbone of the precursor of MPO has a molecular weight of

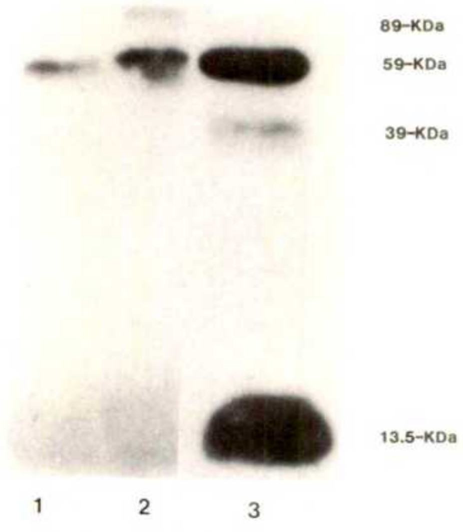

Fig 1. Immunoautoradiographic analysis of MPO peptides. Purified MPO from human PMN (lane 1), undifferentiated HL-60 cells (lane 2), and normal PMNs (lane 3) were electrophoresed into a 13% acrylamide gel and the separated proteins transferred electrophoretically to nitrocellulose paper and the subsequent immunoblot exposed to ^{125}I-protein A. Anti-MPO serum identified predominantly the α (59 kDa) and β (13.5 kDa) subunits of MPO in all three samples. In HL-60 cells and normal PMNs an 89-kDa peptide was evident that was absent from purified MPO.

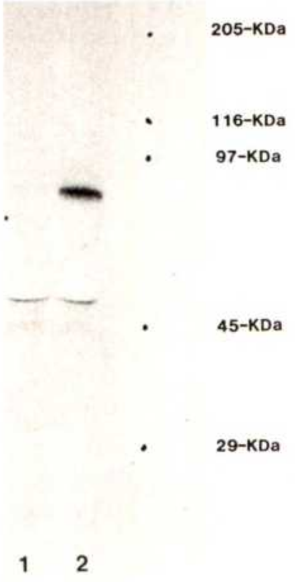

Fig 2. Synthesis of MPO in vitro. A rabbit reticulocyte lysate was supplemented with amino acids (except methionine) and treated with micrococcal nuclease to inhibit translation of endogenous RNA. The lysate was primed with no RNA (lane 1) or 15 μg of RNA isolated from HL-60 cells (lane 2) and proteins labeled with [^{35}S]-methionine. Products were immunoprecipitated with anti-MPO and subjected to SDS-PAGE followed by autoradiography of the dried gel. The primary translation product for MPO synthesis was a single peptide that migrated with a molecular weight of 80 kDa under reducing conditions. Residual activity of endogenous RNA in the reticulocyte lysate accounted for the other labeled proteins seen (lane 1).

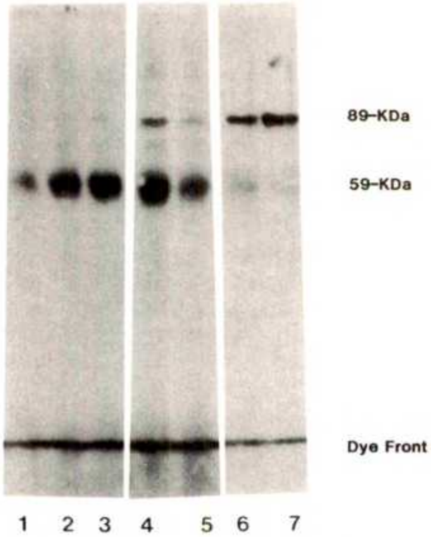

Fig 3. Immunoautoradiographic analysis of MPO peptides in subcellular fractions separated on a gradient of Percoll. Percoll was removed from fractions collected from the gradient prior to separation by SDS-PAGE in a 10% polyacrylamide gel and immunoblotting. Samples from fractions 17 to 19 were electrophoresed in lanes 1 to 3. These fractions contained one of the two major peaks of peroxidase activity and in the immunoblot contained the 59-kDa subunit of MPO. Fractions 22 and 23 were electrophoresed in lanes 4 and 5. These fractions contained the remaining peroxidase activity in the gradient as well as galactosyl transferase and alkaline phosphatase and had both 89-kDa and 59-kDa peptides identified by the immunoblot. Fractions 25 and 26 were the least dense fractions in the gradient and had no peroxidase activity but peak activities for galactosyl transferase and alkaline phosphatase. The immunoblot of these fractions, lanes 6 and 7, contained predominantly the 89-kDa peptide. The 13.5-kDa species migrated with the dye front in a 10% gel.

sufficient size (80 kDa) to account for the α and β subunits (59 + 13.5 kDa) covalently linked into a single polypeptide. After HL-60 cells were induced to differentiate, either by culturing for three days in conditioned medium containing γ-interferon or by culturing for five days in 1.3% dimethyl sulfoxide, their isolated RNA failed to translate for any MPO-related material in vitro (data not shown). Of note, these induced cells still produced functional RNA since the total TCA-precipitable counts from translations primed with RNA from induced cells was higher than control lysates with no RNA added. Thus, this suggests that under the induction conditions used, differentiation was associated with cessation of transcription of the gene for MPO, indicated by the absence of MPO synthesis.

Analysis of subcellular fractions. HL-60 cells were disrupted by nitrogen cavitation and the subcellular organelles separated on a density gradient of Percoll. The immunoblots of individual fractions are shown in Fig 3 and demonstrate that the 89-kDa peptide and the normal subunits of MPO sedimented into separate subcellular fractions. Samples from fractions 17 to 19 from the gradient were electrophoresed in lanes 1 to 3 of the immunoblot shown in Fig 3 and comigrated with the major peak of peroxidase activity. The only MPO peptide detected in this fraction was the 59-kDa α subunit, whereas the β subunit ran at the dye front in the 10% acrylamide gel. Fractions 22 and 23, electrophoresed in lanes 4 and 5 of the immunoblot, contained both the α subunit and the 89-kDa peptide. These fractions contained a small amount of peroxidase activity and comigrated with activity of galactosyl transferase, a marker for *trans*-Golgi. Immunoblots of fractions 25 and 26 contained only the 89-kDa peptide (lanes 6 and 7) and cosedimented with peak activities of galactosyl transferase and alkaline phosphatase, a marker of plasma membrane.

Further work on improving resolution of species in the less dense regions of the gradient is underway,[43] and the identity of subcellular organelles containing 59-kDa and 89-kDa species cannot be absolutely ascertained from this analysis. It is clear from these initial studies that (1) the 89-kDa peptide and mature MPO were in separate subcellular compartments; (2) the 89-kDa peptide was in fractions from the gradient that were less dense than those containing lysosomes and cosedimented with biochemical markers for Golgi and plasma membranes; and (3) the 89-kDa peptide has no peroxidase activity, whereas fractions with the 59-kDa α subunit also had peroxidase activity.

Pulse labeling experiments. Uptake of [^{35}S]-methionine by HL-60 cells starved in a methionine-free medium prior to labeling was rapid, and immunoprecipitable material was detectable after five minutes of labeling (data not shown). In pulse-chase experiments cells were labeled for 30 minutes because these conditions resulted in the greatest number of counts incorporated into an MPO-related peptide without processing of the initial product to more mature species. The earliest labeled peptide immunoprecipitated was an 89-kDa peptide (Fig 4, lane 1).

Pulse-chase experiments demonstrated that this 89-kDa was very slowly processed into normal MPO subunits (Fig 4). Thirty minutes after the addition of cold methionine, a fraction of the 89-kDa species was processed to a 47-kDa peptide intermediate (data not shown) that was further processed to a 39-kDa peptide, the molecular weight of the α subunit of MPO when purified MPO is electrophoresed under nonreducing conditions.[3,11] After five hours of chase the major peptides immunoprecipitated had molecular weights of 89,000, 39,000, and 47,000 (lane 2). Subsequently, the α and β subunits of native MPO were seen after 20 hours of chase, migrating at 59,000 and 13,500 (lane 3). Of note, the predominant species immunoprecipitated were 89-kDa and 39-kDa peptides after a prolonged period of chase (100 hours, lane 5). Samples of immunoprecipitated supernatant contained small amounts of the 89-kDa peptide (data not shown).

Endoglycosidase treatment. Endo H is an enzyme that digests glycoproteins with high-mannose side chains at the proximal *N*-acetylglucosamine-*N*-acetylglucosamine linkage.[44] To characterize the glycosylated intermediates of MPO biosynthesis, immunoprecipitates of extracts from cells pulsed for 30 minutes were treated with endo H. The autoradiography of immunoprecipitated protein incubated in the presence (lane 2) of endo H is shown in Fig 5. The 89-kDa species migrated as a peptide of 79 kDa after treatment with endo H, indicating that the 89-kDa peptide contains high-mannose side chains. In addition, treatment with endo H reduced the 59-kDa subunit to 53 kDa, whereas the 39-kDa species was essentially unchanged. The 39-kDa peptide migrates as a broad band even after digestion with endo H, suggesting that the oligosaccharide side chains on this peptide are heterogeneous and only a fraction are of the high-mannose type. When the autoradiograph is developed sufficiently long to visualize well the 13.5-kDa subunit (not shown), it appeared unaltered by endo H digestion. These observations suggest that the precursor to MPO is glycosylated in the Golgi by the addition of high-mannose side chains to the nascent peptide. In addition, some of the high-mannose side chains are not processed in the Golgi and are present in the α subunit of mature MPO.

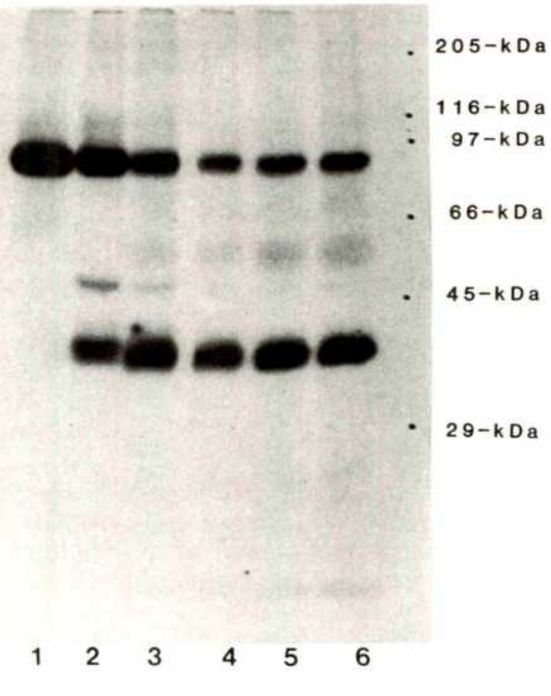

Fig 4. Synthesis of MPO by HL-60 cells. HL-60 cells were starved in methionine-free RPMI 1640 with 10% dialyzed FCS for 30 minutes prior to the addition of [^{35}S]-methionine (100 μCi/mL). Cells were labeled for 30 minutes, after which time a sample was taken (zero chase, lane 1) and cold methionine (final concentration, 1 mmol/L) was added. Samples were taken at 5, 20, 44, 68, and 100 hours (lanes 2 to 6 respectively), immunoprecipitated, reduced, and electrophoresed into a gradient gel (8% to 14% acrylamide and 0% to 14% glycerol). Initially, an 89-kDa peptide was labeled, and it was processed to a 47-kDa intermediate and a 39-kDa peptide that was apparent at five hours of chase (lane 2). After 20 hours of chase (lane 3), the α (59 kDa) and β (13.5 kDa) subunits of mature MPO were identified with a gradual decrease in the 89-kDa peptide.

DISCUSSION

Since first identified as verdoperoxidase by Agner in 1941,[45] MPO has been studied extensively, and its important role in the microbicidal activity of PMNs via the MPO-H_2O_2-halide system has been firmly established.[46] Despite extensive investigation of the structure[2] and function[46] of

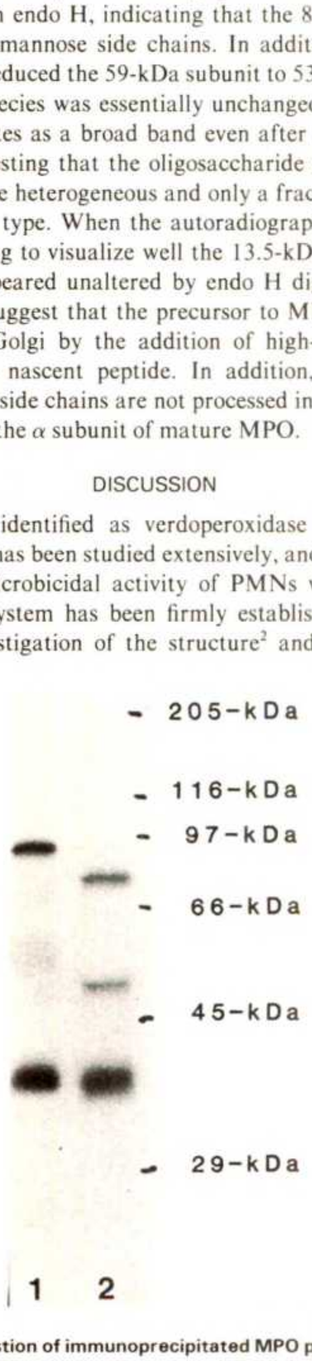

Fig 5. Digestion of immunoprecipitated MPO peptides by endo H. Labeled HL-60 cells that had been chased for 68 hours were immunoprecipitated. The immunoprecipitates were incubated at 37 °C for 24 hours without (lane 1) or with (lane 2) 50 mIU of endo H. Endo H digested the 89-kDa peptide to 79 kDa, the 59-kDa peptide to 53 kDa, and the 39-kDa peptide to 37 kDa, indicating that these glycoproteins contain high-mannose side chains. After more prolonged exposure (not shown), this autoradiograph demonstrated that the 13.5-kDa subunit was resistant to endo H digestion.

MPO, studies of MPO biosynthesis are few in number,[40,41,47] in part reflecting the terminally differentiated state of the PMN characterized by little, if any, protein synthesis.[25] Currently there are at least three general reasons for an interest in MPO biosynthesis.

First, there have been significant advances in understanding cotranslational and posttranslational events during protein synthesis by various types of cells.[48-54] Of relevance to MPO biosynthesis are studies demonstrating the importance of posttranslational modification and phosphorylation of oligosaccharide side chains for the proper transport of lysosomal enzymes from the endoplasmic reticulum to the lysosome.[48-50] Many of the lysosomal enzymes studied to date follow a similar pattern of production and processing. The primary translation product has an amino-terminal sequence that promotes insertion of the nascent peptide through the membrane and into the lumen of the endoplasmic reticulum. As cotranslational events, the insertion sequence is removed by a signal peptidase, and the nascent peptide is glycosylated at the amide nitrogen of certain asparagines in the peptide (*N*-linked glycosylation). Glycosylation is initiated by transfer en bloc of a high-mannose oligosaccharide chain (Glc_3 Man_9 $GlcNAc_2$) from the lipid carrier dolichol to the asparagine. The oligosaccharide side chains are subsequently modified during passage through the Golgi where mannose-6-phosphate residues are incorporated into some of the side chains. These phosphomannosyl groups allow the glycoprotein to bind to the mannose-6-phosphate receptor on the lysosomal membrane and thereby translocate to the lysosome. Hasilek et al[42] have recently demonstrated ^{32}P incorporation by the α subunit during MPO synthesis but were unable to demonstrate mannose-6-phosphate receptors. Newly synthesized glycosylated precursors of lysosomal enzymes, so-called pro forms, are generally larger than the corresponding mature enzyme, and proteolytic conversion to the mature form appears to be closely linked to transport to the lysosome.[39,51]

The second reason to examine MPO biosynthesis is that production of MPO is closely linked to myeloid differentiation.[40,41] Two recent studies have demonstrated that MPO synthesis by promyelocytic HL-60 cells ceases when the cells are chemically induced to differentiate to more mature cells, either macrophages or granulocytes.[40,41] The induced cells had no MPO-specific mRNA as assessed in an in vitro translation system, although functional RNA was still transcribed by induced cells. This suggests that cessation of transcription of the MPO gene is responsible for the termination of MPO synthesis seen during myeloid differentiation. These studies of MPO biosynthesis may provide information on the control mechanisms for protein synthesis during myeloid differentiation and insight into events associated with abnormal differentiation in neoplasia.

The third reason to study MPO biosynthesis is to examine the genetic basis for MPO deficiency, a common hereditary disorder of PMNs.[12] In a previous study,[3] sensitive immunoblot analysis of peroxidase-deficient PMNs separated by PAGE demonstrated that MPO-deficient PMNs lack the normal α and β chains of MPO but contain an MPO-related 89-kDa peptide that is also present in normal PMNs. The presence of this 89-kDa peptide is consistent with the hypothesis that MPO deficiency reflects a failure of developing myeloid cells to compartmentalize MPO into azurophilic granules, perhaps secondary to defective posttranslational processing of the enzyme precursor.

Studies presented here suggest that biosynthesis of MPO likely follows the same general pattern previously outlined for other lysosomal enzymes. The nonglycosylated primary translation product synthesized in vitro had a molecular weight of 80,000 and is thus a peptide of sufficient size to accommodate the α and β chains of mature MPO (59 kDa + 13.5 kDa) linked covalently into a single precursor. The earliest form of MPO synthesized in vitro in pulse experiments was an 89-kDa protein identified within five minutes of labeling. Treatment of the 89-kDa peptide with endo H, an enzyme that cleaves between proximal *N*-acetylglucosamine groups on high-mannose side chains, resulted in a 79-kDa peptide, demonstrating the presence of high-mannose side chains on the 89-kDa peptide. In preliminary experiments (data not shown), HL-60 cells labeled in the presence of tunicamycin, an antibiotic that prevents the initial transfer of the high-mannose oligosaccharide from dolichol to the nascent peptide backbone,[55] produced a core peptide of 75 to 77 kDa. This core glycosylation occurred very early in biosynthesis and was very likely a cotranslational event whereby the signal peptide was removed from the 80-kDa primary translation product and the core peptide of approximately 77 kDa glycosylated at selected asparagines to produce the 89-kDa peptide, although there is no direct evidence for a signal peptide presented here. The 89-kDa species was identified in immunoblot analysis of subcellular fractions of HL-60 cells separated in a discontinuous gradient of Percoll. This peptide was localized in a subcellular organelle(s) that was less dense than lysosomes and that cosedimented with enzyme markers for Golgi and plasma membrane.

When labeled HL-60 cells were chased with a 1,000-fold excess of unlabeled methionine, the 89-kDa peptide was slowly processed, first to an intermediate 47-kDa peptide that was converted to a 39-kDa peptide beginning within two hours of chase (data not shown). After five hours of chase, the α and β subunits of mature MPO were immunoprecipitated, although the 39-kDa peptide remained prominent late into the chase phase. The 89 kDa was processed very slowly and was still present after 100 hours of chase. The relatively slow rate of processing of the MPO precursor has been noted by Hasilek et al who recently reported persistence of the precursor glycoprotein after as late as 70 hours of chase.[42]

In preliminary experiments, SV8 protease digestion of the 89-kDa species generated seven peptides of mol wt <49,000, as did digestion under identical conditions of the immunoprecipitation after 24 hours of chase (data not shown). The persistence of the 89-kDa peptide late into the chase makes it impossible to compare a proteolytic digest of isolated 89 kDa with that of isolated 59-, 39-, and 13.5-kDa subunits. Kinetics of labeling in the pulse-chase experiments coupled with these findings are sufficient evidence for a product-precursor relationship between the 89-kDa peptide and mature MPO. In fact, few examples exist in the literature of such a relationship substantiated by peptide or sequence analysis of the precursor and the product,[56] although studies are currently underway toward that end.

Endo H treatment modified the 89-kDa glycoprotein to a 79-kDa peptide regardless of the time during the chase at which the 89-kDa material was immunoprecipitated, indicating persistence of the high-mannose side chains on the 89-kDa peptide. Digestion of the processed peptides with endo H demonstrated that the α subunit has susceptible high-mannose side chains and was deglycosylated to a 53-kDa peptide. In contrast, the β subunit appeared unaffected by endo H treatment. These findings extend a recent study by Olsen and Little[11] in which they reported the results of deglycosylation of the purified subunits of MPO using trifluoromethanesulphonic acid. With this treatment the α subunit (57 kDa in their study) was converted to 52 kDa, whereas the β subunit was unchanged. Therefore not only are the carbohydrate side chains in MPO limited to the α chain but they are primarily high-mannose oligosaccharides.

Purified MPO has subunits of 59 kDa and 13.5 kDa in a 1:1 ratio,[3-8] but under nonreducing conditions has subunits of 59 kDa, 39 kDa, and 13.5 kDa in a 1:1:2 ratio.[9] The 39-kDa species has been observed by numerous investigators studying MPO structure,[3,4,5,11,47,57] but there is no consensus as to its relationship to the α and β chains of MPO. Investigators have attributed its presence to anomalous migration of unreduced 59-kDa peptide in polyacrylamide gels,[57] boiling samples in SDS prior to electrophoresis,[47] reducing samples for electrophoresis during or after heat treatment,[11] proteolytic digestion of the 59-kDa peptide,[4] and contamination of the MPO. Two-dimensional maps of chymotryptic digests of iodinated 59-kDa and 39-kDa species separated by PAGE are similar but not identical[9] and clearly demonstrate that these species are very closely related. Data presented here demonstrate the differences in the carbohydrate composition of the 59-kDa and 39-kDa species, the latter being relatively insensitive to endo H. Although the interrelationship between the 59-kDa and 39-kDa species is still the subject of ongoing work, the 39-kDa peptide was the predominant species during pulse-chase experiments.

The data presented here provide a foundation for further examination of MPO synthesis, processing, and packaging in normal myeloid cells. The findings presented are consistent with the hypothesis that the genetic defect underlying MPO deficiency is different from that previously proposed.[13-18] The presence of the 89-kDa MPO-related glycoprotein in MPO-deficient PMNs suggests that the deficient cells express the gene for MPO synthesis but that some event in the cotranslational/posttranslational processing is defective. This defect results in production of an aberrant form of MPO that, because of abnormal processing, is not packaged in the azurophilic granules during the promyelocytic stage of development. Small amounts of pro-MPO remain in the vestigial Golgi of peripheral blood PMNs where it appears as the faint band at 89 kDa when normal and MPO-deficient PMNs are analyzed by immunoblotting.[3] MPO-deficient cells, which might be expected to contain larger amounts of pro-MPO as a reflection of faulty processing, may behave in a fashion akin to fibroblasts in I cell disease.[58] The latter lack *N*-acetylglucosamine phosphotransferase and therefore are unable to produce the recognition marker mannose-6-phosphate for transport of lysosomal enzymes. In the absence of the necessary targeting structures to direct and transport the proteins correctly to the lysosome, the aberrant form of the lysosomal enzyme is released from the cell into the medium rather than properly stored in the lysosome. In an analogous manner, promyelocytes of MPO-deficient individuals may secrete relatively large amounts of pro-MPO into their immediate environment in the bone marrow. Work is in process to test this hypothesis in order to identify the genetic defect in hereditary MPO deficiency.

ACKNOWLEDGMENT

I wish to express my gratitude to the late Dr Edward Heath and Dr Kathy Anderson of the Department of Biochemistry, University of Iowa, for careful guidance during the initial phases of this work and valuable advice throughout, Dr Robert Karr for helpful suggestions, Dr Peter Densen for review of this manuscript, and Dr Robert A. Clark for insightful criticism and for review of this manuscript.

Isolation of Circumferential Microtubules From Platelets Without Simultaneous Fixation

By James G. White, E. Radha, and Marlys Krumwiede

Circumferential bands of microtubules (MT) support the discoid shape of resting platelets and participate with the contractile apparatus in shape change and internal contraction following activation. Elucidation of interactions between the circumferential coils and proteins of the stable and contractile cytoskeleton is essential for understanding MT function in platelet physiology. A previous investigation demonstrated that the circumferential rings can be isolated intact from resting platelets following simultaneous exposure to glutaraldehyde and Triton X-100. However, the use of fixation prevented the characterization of protein interactions. The present study has circumvented this problem by developing a procedure for isolating intact microtubule coils from detergent-treated platelets without the use of fixative agents. Incubation of the platelets for intervals of 30 to 60 minutes with the microtubule-stabilizing agent taxol preserved the circumferential bundle after extraction with Triton X-100 even after washing five times. The procedure has made it possible to carry out protein studies on isolated microtubule rings and associated proteins.

©1986 by Grune & Stratton, Inc.

THE CIRCUMFERENTIAL microtubule (MT) is an important constituent of the platelet cytoskeleton. It supports the discoid shape of resting platelets[1-3] and participates in the process of internal contraction when the cells are stimulated.[4,5] The precise mechanisms through which circumferential MT exert these functions, however, are unclear.[6]

To evaluate the role of the circumferential MT in platelet physiology, we have recently developed a procedure for isolating intact MT coils from platelets in suspension.[7] The method has been useful for studying the fate of MT in activated platelets,[8] but biochemical and physiologic experiments have been limited because glutaraldehyde was needed in the preparative procedure. In recent investigations we have found a way to avoid the presence of a fixative during the separation of MT coils from suspended platelets. The addition of a relatively large concentration of taxol,[9] an MT-stabilizing agent, obviated the need for glutaraldehyde and permitted the recovery of large numbers of MT coils in a nearly native state.

MATERIALS AND METHODS

General. After informed consent, blood was obtained from healthy adult donors whose platelets had been evaluated in many previous studies from our laboratory.[4,10,11] Samples obtained by venipuncture were mixed immediately with citrate-citric acid, pH 6.5 (93 mmol/L sodium citrate, 70 mmol/L citric acid, and 140 mmol/L dextrose), in a ratio of nine parts blood to one part anticoagulant. Platelet-rich plasma (PRP) was separated from whole blood by centrifugation at 100 g for 20 minutes at 23 °C and maintained at room temperature until used in specific experiments.

Concentration of platelets. Adenosine (5 mmol/L) and theophylline (3 mmol/L) were added to the citrate anticoagulant described previously to inhibit platelet activation.[12] Five milliliters of PRP were combined with an equal volume of the citrate anticoagulant and centrifuged at 1,500 g for 30 minutes to obtain pellets. The supernatant was decanted and the platelets gently resuspended in 1 to 2 mL of PRP. Concentrated samples were maintained in suspension at room temperature. The procedure resulted in a three- to four-fold concentration of platelets, and a substantial proportion of the cells were discoid after resuspension in PRP.

Samples of concentrated PRP, 0.5 mL in volume, were combined with taxol,[9,13,14] an MT-stabilizing agent, at a final concentration of 2×10^{-4} mol/L. Taxol was obtained from the Natural Products Branch, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, Md. The agent was dissolved in dimethyl sulfoxide at a concentration of 10 mmol/L. The platelets were incubated with taxol for one hour before lysis.

Platelet lysis. A buffer designed by Small[15] to preserve cytoskeletal elements (NaC1, 127 mmol/L; KCl, 5 mmol/L; Na_2HPO_4, 1.1 mmol/L; KH_2PO_4, 0.4 mmol/L; $NaHCO_3$, 4 mmol/L; glucose, 5.5 mmol/L; $MgCl_2$, 2 mmol/L; ethylene glycol tetra-acetic acid, 2 mmol/L; piperazine-N,N^1-Gis (2-ethanesulfonic acid) (PIPES), 5 mmol/L; pH 6.0 to 6.1) was combined with Triton X-100 (Sigma, St Louis) at a final concentration of 10%. A 100-μL volume of this solution was combined with 0.5 mL of taxol-treated, concentrated platelets. The detergent caused almost immediate clearing of the cloudy cell suspension.

Preparation of whole mounts. Single drops of the extracted platelets were placed on formvar-coated, carbon-stabilized grids for 2½ minutes, rinsed with cytoskeleton buffer, and examined unfixed or after postfixation for two or more hours in 2.5% glutaraldehyde in the same buffer.[16,17] Grids were then rinsed twice with distilled water and drained briefly on the edge with filter paper. Finally, the grids were passed through four drops of 3% sodium silicotungstate, drained of excess stain, and allowed to air dry.[15]

Preparation for scanning electron microscopy. Large drops of the supernatant from extracted platelets were mounted on circular glass disks. In addition, the lysate and samples of washed, resuspended MT were deposited on millipore filters. After contact with surfaces for 2½ minutes, they were rinsed with cytoskeletal buffer and postfixed in 2.5% glutaraldehyde as previously described for whole mount preparations. The coils were then dehydrated in a graded series of alcohols, substituted with freon, and dried by the critical point method of Anderson in a Bomar apparatus (Bomar Instruments, Tacoma, Wash).[18] After coating with a 50 Å layer of carbon and gold, the coils were examined in a Cambridge S4D-10 scanning electron microscope (Cambridge Instruments, Cambridge, England).

Preparation for polyacrylamide gel electrophoresis (PAGE). Six to eight detergent-extracted, 0.5-mL platelet samples were combined and centrifuged to obtain a pellet. Clear supernatant was discarded and the pellet resuspended in Hanks' balanced salt solution (HBSS) containing taxol at 2×10^{-4} mol/L. The washing procedure was repeated five times and the final pellet resuspended in 0.5 mL of HBSS with taxol. The protein content of the platelet concentrate and isolated MT coils was measured by the method of Lowry et al.[19] Sodium dodecyl sulfate (SDS)-PAGE was performed according to the method of Laemmli.[20] A gradient slab of 8% to 15% was used for analyzing the protein profile.[21] The samples were dissolved in an SDS sample buffer and boiled for two minutes. Protein standards were electrophoresed for molecular weight estimations. Gels were stained with brilliant Coomassie blue R and scanned with a Kratos spectrodensitometer (Kratos Analytical Instruments, Westwood, NJ) connected to a Hewlett-Packard integrator (Hewlett-Packard, Palo Alto, Calif).

Immunoblot preparation. PAGE gels of the isolated MT coils prepared as previously described were transferred to nitrocellulose electrophoretically according to the method of Towlin et al.[22] After blotting, the nitrocellulose was incubated with gelatin to block nonspecific protein-binding sites. The blot was then incubated with a monoclonal antibody to β-tubulin of mouse origin (Cooper Biomedical, Malvern, Pa). The immune complex was detected with peroxidase-labeled antibody to mouse IgG after incubation in 4-chloro-1-napthol.

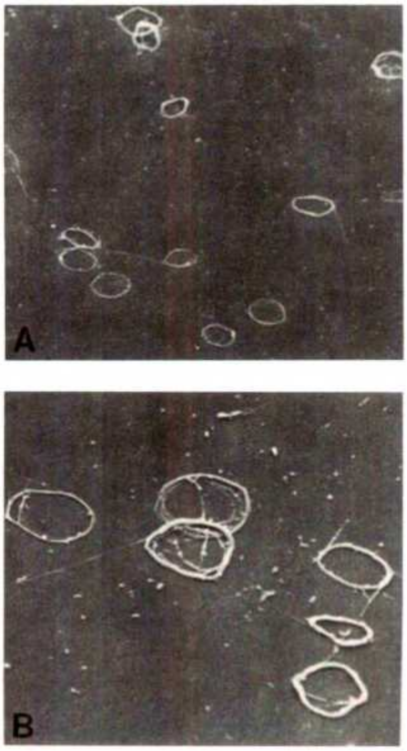

Fig 1. Low- and high-magnification scanning electron micrographs of isolated marginal band MT. The MT coils have retained their concentric organization throughout the isolation procedure and multiple washings and appear randomly dispersed on the surface of the disks. Membranes and cytoplasmic constituents are virtually absent from the coiled MT. Original magnifications (A) ×2,600; (B) ×6,500; current magnifications (A) ×1690; (B) ×4225.

RESULTS

Morphology. MT coils recovered by detergent lysis from platelets incubated for an hour with a high concentration of taxol were essentially identical in appearance to the coils isolated from platelets after simultaneous exposure to detergent and glutaraldehyde fixative. Examination of glass disks (Figs 1A and 1B) and millipore filters (Figs 2A and 2B) in the scanning electron microscope revealed fields that were virtually free of any other structures but MT coils. Whole-mount preparations viewed in the transmission microscope were also nearly devoid of cellular debris. MT coils consisted of several concentric rings, ranging from three to 12 with a median of eight. Two free ends were observed extending from some coils, but multiple free ends were also common (Figs 3A and 3B). MT coils were more loosely arranged in the absence of glutaraldehyde fixation during isolation or mounting, but the basic circular configuration of the loops was well maintained in most examples.

Biochemistry. Depending on the amount of protein applied to the gel, SDS-PAGE of proteins solubilized from multiply washed MT rings revealed a dense single or double band migrating with the same mobility as the tubulin standard (Fig 4). In addition to tubulin, several other proteins were evident on the gels. A band at approximately 210 K may represent an MT-associated protein (MAP). Two or three additional protein bands with apparent molecular

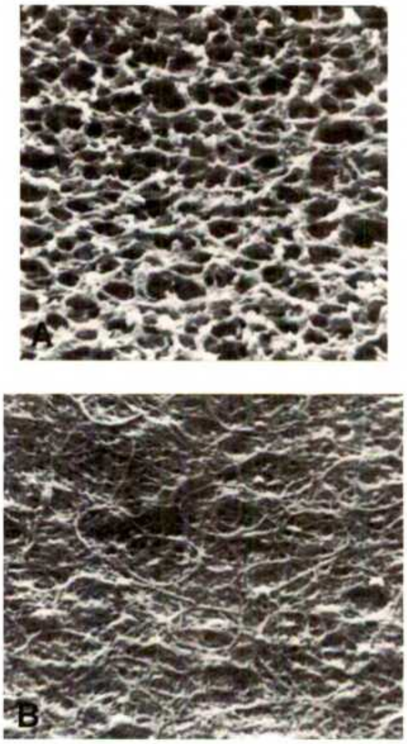

Fig 2. Scanning electron photomicrographs of nucleopore filters. (A) The filter has not been exposed to MT. (B) The surface has been exposed to the multiply washed and resuspended MT obtained from eight samples of detergent treated platelet concentrate, each 0.5 mL in volume. The surface is buried in coils. Original magnifications ×6,000; current magnifications ×3900.

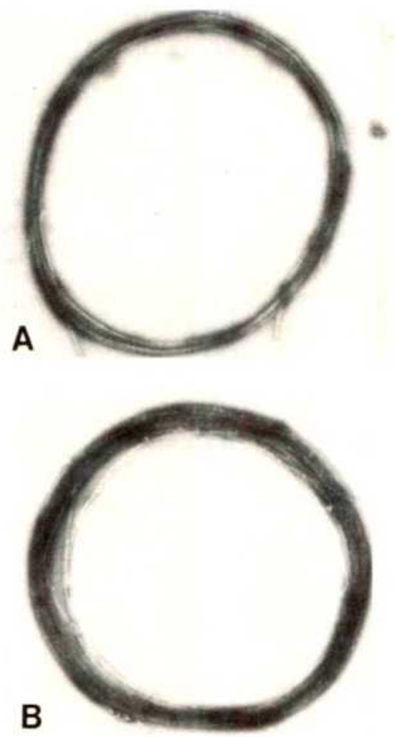

Fig 3. Negative-stain whole mounts of MT coils prepared without glutaraldehyde fixation from detergent-treated platelets after repeated washing and resuspension. The tightly coiled appearance is well preserved in the two examples. More than two loose ends are visible on each coil, but the increase may be due to fracture during preparation. Original magnifications ×18,000; current magnifications ×11,700.

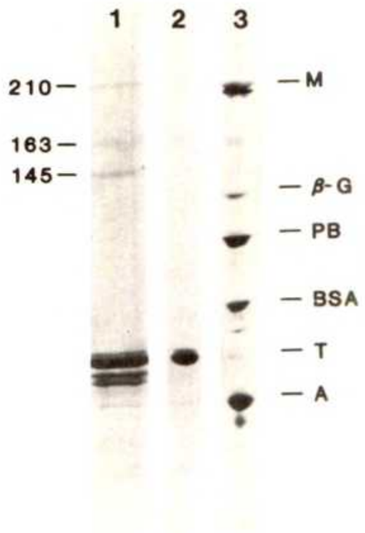

Fig 4 SDS-PAGE (5% to 15% gradient) separation of proteins solubilized from isolated MT coil preparation after five washings and resuspensions in HBSS (channel 1). The gels were stained with brilliant Coomassie blue R. Channel 2 contains partially purified brain tubulin (T), and channel 3 contains several standard proteins for molecular weight estimation, including myosin (M), β galactosidase (3G), phosphorylase B (PB), bovine serum albumin (BSA) and actin (A). α- and β-tubulin are not well separated in the standard or experimental samples because of the high protein concentration. A protein band at approximately 210,000 mol wt on the experimental gel may represent an MT associated protein like MAP.[2] The nature of the other HMW proteins is not known. The actin band is usually more prominent in the experimental gels. Several protein bands between actin and tubulin remain with isolated coils throughout isolation and washing procedures. They may represent LMW MAPs.

weights above 100,000 may represent breakdown products of high–molecular weight (HMW) proteins since proteolytic inhibitors were not included during lysis or washing. A low–molecular weight (LMW) band with the mobility of the actin standard was constantly present. Between tubulin and actin were two or three bands that may represent LMW MAPs. Immunoblots prepared from the isolated MT coils, incubated with a monoclonal antibody to tubulin, and stained with a peroxidase labeled second antibody revealed a specific reaction with platelet tubulin (Fig 5).

Densitometry of PAGE gels revealed that tubulin constituted 43% to 48% of the protein on the gels. Measurement of the protein content of the concentrated platelet suspension and multiply washed MT coils, adjusted on the basis of the densitometric observations, revealed that tubulin constituted about 3.3% to 3.8% of the total platelet protein.

DISCUSSION

The present report has described a relatively simple way to stabilize the circumferential MT supporting the discoid shape of resting platelets during isolation and purification. Taxol, an MT-stabilizing agent,[9] was added to platelet suspensions at twice the concentration used in previous studies.[13,14] Platelets were incubated for an hour and then lysed in a cytoskeletal buffer containing Triton X-100. The presence of taxol prevented disassembly and disorganization of MT coils during rupture of the cell membranes by detergent. Examination of glass disks prepared for scanning electron microscopy after contact with drops of the lysed platelet suspension for 2½ minutes revealed MT coils evenly distributed on the surface. Millipore filters on which MT coils isolated from 4 mL of cleared suspension had been deposited were completely covered by coils. Thus, the procedure appears to provide a simple way to obtain susbstantial numbers of MT coils for evaluation without requiring the use of glutaraldehyde or other fixatives.[7]

The morphology of unfixed MT coils was generally well preserved by the pretreatment with taxol. The loops making up the MT coils had separated in some examples, but in most the resemblance to a lariat was well preserved. The number of free ends of MT extending from the coils was variable. Fracture of the delicate structures during attachment to grids and glass coverslips or in the process of air or critical-point drying may have caused some disruption.[7] However, survival of the basic concentric configuration suggests that cohesive forces may be involved in holding loops of the coiled MT together. The nature of these forces is not known but may involve one or several types of MAPs.[23-25]

SDS-PAGE proteins solubilized from the multiply washed MT coils revealed a prominent tubulin band identical in

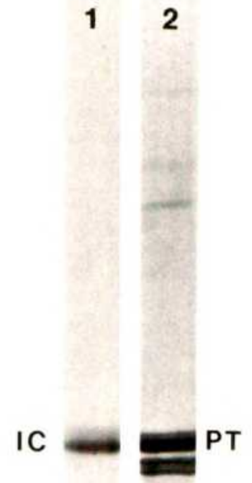

Fig 5. An immunoblot (channel 1) transferred from a PAGE gel of isolated MT coils prepared as described in the text and shown in Fig 4. The blotted proteins were stained with a monoclonal antibody to tubulin followed by a peroxidase-coupled second antibody to the immune complex (IC). Only the protein band (channel 2) identified as platelet tubulin (PT) by its comigration with standard MT protein in the previous Figure is stained by the peroxidase-coupled antibody.

mobility to the brain-derived standard. Immunoblotting and staining with a monoclonal antibody to tubulin confirmed that the band was authentic MT protein. Despite the multiple washings and resuspensions in buffer, several other protein remained associated with MT coils. Both HMW and LMW proteins, including one with a mobility identical to the actin standard, were present in the gels. One of the HMW proteins had a mobility similar to an MAP described previously in platelets and other cell types.[23-25] Two or three protein bands lying between actin and tubulin may also represent MAPs. Studies to characterize these proteins are continuing.

Analysis of the gels by densitometry revealed that tubulin constituted approximately 40% to 50% of the total. Based on protein determinations on the concentrated platelet suspension and the multiply washed coils, the amount of tubulin recovered constituted about 3.3% to 3.8% of the total platelet protein. The recovery obtained in this study agrees well with the figure of 3.1% reported by Steiner and Ikeda.[26]

Taxol has been used previously to facilitate isolation of MT and MAPs from other cell types.[27] However, the procedure involving taxol was used primarily to separate MAPs from MT reassembled after earlier isolation of tubulin from calf brain. The present investigation appears to be the first study to use taxol for maintenance of MT organization observed in the intact cell during isolation and multiple washing. As a result, the proteins remaining in an insoluble state with isolated MT during washing may be very important to MT function in intact platelets. Studies to identify and characterize these proteins by immunoelectron microscopy are in progress.

NOTE ADDED IN PROOF

Following acceptance of this manuscript, a report using a similar approach to isolating the platelet circumferential microtubule has appeared (Kenney DM, Linck RW: The cytoskeleton of unstimulated platelets: Structure and composition of the isolated marginal microtubular band. J Cell Sci 78:1, 1985).

On the Interaction of Rabbit Antithrombin III With the Luminal Surface of the Normal and Deendothelialized Rabbit Thoracic Aorta In Vitro

By Mark W.C. Hatton, Sue L. Moar, and Mary Richardson

Pure rabbit antithrombin III was isotope labeled (with ^{125}I or ^{3}H) by two different methods; neither procedure caused a loss of antithrombin activity although both methods affected the affinity of the protein for Sepharose-heparin. From segments from freshly excised rabbit aorta, the uptake of isotope-labeled antithrombin III by the endothelium was rapid and saturable, although relatively small compared to the uptake of thrombin; binding of ^{3}H-antithrombin III to the endothelium resembled that of ^{125}I-antithrombin III. Transendothelial passage of antithrombin III into the subendothelial layers (intima-media) was slow and progressive. Endothelium binding was not affected by pretreating the vessel with either heparin, thrombin, or glycosaminoglycan-specific enzymes. Endothelium-bound antithrombin III was not selectively displaced by either heparin or thrombin. In contrast, endothelium-bound thrombin was rapidly dislodged by antithrombin III as a thrombin–antithrombin III complex. The surface of the deendothelialized aorta (ie, subjected to a balloon catheter) bound antithrombin III avidly. Pretreatment of the deendothelialized vessel with glycosaminoglycan-specific enzymes, particularly heparitinase, decreased intima-media binding by up to 80%. ^{125}I-antithrombin III, when bound to the deendothelialized vessel surface, was actively displaced by either heparin, thrombin, or by unlabeled antithrombin III. The relatively poor binding of antithrombin III compared with that of thrombin by the endothelium in vitro supports an earlier proposal (Lollar P, Owen WG: J Clin Invest 66:1222–1230, 1980) that thrombin bound to high-affinity sites, possibly pericellular proteoglycan, of the endothelium is inactivated by plasma antithrombin III in vivo. Such a situation probably holds for large arteries at least.

© 1986 by Grune & Stratton, Inc.

IN 1973, Rosenberg and Damus proposed that heparin, a glycosaminoglycan with potent anticoagulant properties, interacted specifically with a plasma protein, antithrombin III, which in turn assumed a state of activation[1]: activated antithrombin III, complexed with heparin, availed itself more readily for reaction with various proteases that arose during hemostatic imbalance to accelerate the anticoagulation process.[2] Recently, Marcum et al[3] have explored in vivo the role of proteoglycans of the vessel wall of the microvasculature[4] in the inhibition of thrombin by antithrombin III. No direct measurements of antithrombin III binding to the endothelium were reported, but speculation was made that such an interaction with pericellular heparinlike proteoglycans takes place.

A study of the binding of, and interaction between, thrombin and antithrombin III to different immobilized glycosaminoglycans showed that, whereas the enzyme bound strongly to either heparin, heparan sulphate, or dermatan sulphate, antithrombin III bound only to heparin.[5] However, numerous analyses of blood vessel glycosaminoglycans have revealed the presence of both heparan sulphate and dermatan sulphate, but not heparin, in the intima-media of arteries.[6] Also, heparan sulphate and dermatan sulphate have both been identified from the extracellular matrix of cultured endothelial cells.[7,8] We proposed[5] that probably thrombin was attracted by pericellular proteoglycan at the endothelial surface and that plasma antithrombin III reacted rapidly with the proteoglycan-bound enzyme. The proposal, which in many ways complemented earlier models[9–11] for the role of heparin in the thrombin–antithrombin III reaction, was supported by a report from Awbrey et al[12] that thrombin had a great affinity for cultured endothelial cells. Later studies showed that thrombin bound strongly to the luminal surface of blood vessels[13,14] and that endothelium-bound thrombin became inactivated rapidly by antithrombin III.[15,16]

Recently, Stern et al[17] have reported that bovine ^{125}I-antithrombin III bound in a specific, time-dependent manner (5.4×10^4 molecules bound/cell at saturation) to bovine aorta endothelium. In contrast, we observed relatively poor binding of rabbit ^{125}I-antithrombin III to rabbit aorta endothelium using a Hautchen technique as a means for direct measurement of endothelium-bound ligand.[18] Furthermore, relatively poor or negligible binding of this protein to cultured endothelial cells from bovine aorta[19] or cornea[20] has been reported. In the following report we have compared the binding of rabbit antithrombin III for the luminal surface of the normal and deendothelialized (ballooned) rabbit thoracic aorta, considered the possible role of pericellular proteoglycan in the binding, and measured some of the properties of endothelium- and subendothelium-bound antithrombin III.

MATERIALS AND METHODS

Materials. The following were obtained from Sigma Chemical Co (St Louis): heparin, dermatan sulphate, nonspecific protease (from Streptomyces griseus), HEPES, protamine, and bovine serum albumin (Cohn Fraction V; BSA). Modified Eagle's medium (MEM) was purchased from GIBCO (Burlington, Ontario); heparitinase, chondroitinases, AC and ABC (all products of Seikagaku Kogyo Co Ltd, Tokyo), and rabbit serum albumin (RSA) were obtained from Miles Inc (Elkhart, Ind); Arvin was from Berk Pharmaceuticals Ltd (Guildford, Surrey, UK), Thrombostat from Parke-Davis Co (Detroit), Enzymobeads from Biorad Ltd (Mississauga, Ontario), S-2238 from Kabivitrum (Stockholm), and Na pentobarbital (Somnotol) from MTC Pharmaceuticals (Hamilton, Ontario).

Na ^{125}I, NaB^{3}H$_4$, and ACS scintillation fluid were purchased from

Amersham Corp (Oakville, Ontario); NCS tissue solubilizer was from NEN (Lachine, Quebec), and Sepraphore (cellulose-acetate chromatographic strip) was obtained from Gelman Sciences Inc (Ann Arbor, Mich).

Purification of bovine thrombin and rabbit antithrombin III. An ion exchange procedure that was reported originally for isolating thrombin from citrated plasma[21] was modified slightly to purify the enzyme from Thrombostat.[5] The procedures used for determining various properties (ie, purity, activity) of thrombin preparations have been described before.[13,22] The procedure for preparing antithrombin III has been described before.[11,18] Approximately 6.3 mg (±0.5 mg SEM, n = 5) of antithrombin III was obtained from 100 mL of rabbit acid-citrate-dextrose (ACD) plasma using Sepharose-heparin affinity chromatography.[23] Each preparation was assessed for purity by sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis.[24] Using loads up to 45 μg, rabbit antithrombin III presented as a single band (mol wt, approximately 63,000) when stained with Coomassie brilliant blue. Immunodiffusion against antiserum to rabbit antithrombin III raised in sheep produced one precipitin line that, after fixation, stained strongly with Coomassie brilliant blue. Lastly, using S-2238 as a substrate for measuring active thrombin,[25] purified antithrombin III (21 pmol/mL of 0.1 mol/L Na phosphate, pH 7.4) caused 60% to 70% inactivation of thrombin (10 pmol/mL) in ten minutes at 37 °C. The addition of heparin (0.5 μg/mL) to this antithrombin III–thrombin mixture produced total inactivation in less than one minute, whereas dermatan sulphate (0.5 μg/mL) did not significantly alter the rate of thrombin inhibition by antithrombin. From these data, antithrombin III was considered to be active as an inhibitor and essentially free from contaminants, including heparin cofactor II. Calculations of protein concentrations were made using $E^{1\%}$ (280) values of 10.5 and 16.2 and molecular weights of 63,000 and 36,000 for antithrombin III and α-thrombin respectively.[1,11]

Radiolabeling of proteins. Iodination, using Enzymobeads, was carried out as suggested by the supplier, Biorad Ltd. Approximately 20 to 50 μg of protein was labeled (30 minutes, 23 °C), centrifuged, and then dialyzed in the presence of 200 μL of 4% RSA-MEM (see the following material) for 16 to 20 hours (4 °C) against MEM (250 mL × 4) as described previously.[22]

Tritiation of antithrombin III was performed using a derivation of the technique of Rice and Means.[26] Approximately 20 to 35 μg (150 μL) of antithrombin III (in 0.3 mol/L Na phosphate, pH 8.0) was added to 10 μL formaldehyde (1.2 μmol) cooled in an ice bath that was placed in a glove box. After standing for one hour, 10 to 20 μL of NaB^3H_4 (1 to 4 μCi) in 0.1 mol/L NaOH was added. Reaction was allowed to progress for ten minutes at 0 °C and then stopped by adding approximately 50 μL glycerol and 0.5 mL 0.3 mol/L Na phosphate (pH 6.0). After one hour at room temperature, the mixture was added to a dialysis bag (diameter, 0.6 cm) containing 200 μL of 4% RSA-MEM (to prevent losses of ^3H–antithrombin III because of adsorption). Dialysis against 250 mL of 0.15 mol/L NaCl and then 250 mL (× 3) of MEM was carried out over 20 hours (4 °C).

All radiolabeled proteins were stored at 4 °C and were used for binding studies for up to four days from the date of labeling. Antithrombin activities of the radiolabeled samples were compared with unlabeled antithrombin III to determine any damaging effects of radiolabeling. The activities were measured by incubating various quantities of a radiolabeled antithrombin III preparation with 8 to 10 IU of α-thrombin for ten minutes at 23 °C; residual thrombin activity was measured by a plasma-clotting assay.[27]

Preparation of defibrinogenated, recalcified rabbit plasma. Blood was collected through a carotid artery cannula into ACD (ratio [vol/vol] of blood to anticoagulant, approximately 9) and centrifuged (9,000 rpm; 30 minutes) to yield ACD plasma. ACD plasma (25 mL) was treated with Arvin (0.1 mL containing 6 IU) for three hours (37 °C). The fibrin clot was removed, and the plasma supernatant was dialyzed against MEM (250 mL × 2) at 4 °C for 20 hours.

Uptake of radiolabeled proteins by the thoracic aorta. New Zealand White male rabbits, weighing between 2.3 and 3.3 kg, were used. The procedures for anesthetizing and heparinizing the animal before slaughter, cannulation (left carotid artery) leading to exsanguination, the excision and flushing of the vessel, and the postexcision handling (ie, defatting of the adventitia) have been described in detail previously.[22] When required, the aorta was deendothelialized after exsanguination by using a Fogarty balloon catheter (Edwards Laboratories Inc, Santa Ana, Calif) as described before.[22]

The glycosaminoglycan-specific enzymes used in these experiments were tested first for contaminating protease activity using ^{125}I-labeled, denatured casein as described before.[28] Only protease-free samples of heparitinase and the chondroitinases were used for aorta treatment. Data on the glycosaminoglycan specificity of each enzyme was supplied by the manufacturer and was not investigated further. Thus, heparitinase was essentially free from heparinase and chondroitinase activities, and chondroitinase AC was free from heparin-, heparan-sulphate–, and dermatan sulphate–degrading activities. Chondroitinase ABC was without activity on heparan sulphate or heparin.

Measurements of the uptake of radiolabeled antithrombin III were performed with 1-cm aorta segments immersed in 1 mL of 4% RSA-MEM, pH 7.4, at 37 °C. For pretreatment experiments, an aorta segment was incubated with a reagent contained usually in 1 mL of 4% RSA-MEM. After treatment, the segment was washed for one minute in MEM (4 mL) before measuring the uptake of the labeled protein. In displacement experiments, after exposure to the labeled protein the segment was rinsed in MEM (4 mL, one minute) and then incubated with the displacing agent, usually in 1 mL 4% RSA-MEM.

After treatment, each vessel segment was separated into three layers: the endothelium by Hautchen preparation (using cellulose acetate strips as described by Pugatch and Saunders[29]), the underlying intima-media, and the adventitia. The latter two layers were separated using cilia forceps. The wall layers were counted for γ- or β-radioactivity as described before.[18,22] Also, radioactivity released from the vessel wall into the medium was counted and analyzed by gel filtration chromatography.

Gel filtration chromatography. To compare the product released from the vessel wall with the initial labeled protein, the displaced radioactivity (in 1 mL 4% RSA-MEM) was immediately frozen and, occasionally, freeze-dried. The reconstituted sample (1-mL vol) was then loaded onto a Sephadex G-200 column (60 cm × 1 cm) equilibrated with 0.01 mol/L Tris-HCl/0.15 mol/L NaCl, ph 7.4; fraction volume was 1.2 mL.

Examination of the aorta wall components after Hautchen preparation. Aorta segments (1-cm length) were opened by cutting along the long axis, and the endothelium was removed on cellulose acetate film. The endothelium, attached to the celluose acetate film, and the remaining vessel wall were fixed in 2.5% glutaraldehyde in 0.1 mol/L Na cacodylate, pH 7.0, and prepared for transmission (TEM) and scanning electron microscopy (SEM) by standard techniques.[30] Cellulose acetate–endothelium preparations were also prepared for light microscopy by staining with 0.07% toluidine blue (10 seconds at 23 °C), rinsing in water, air-drying, and mounting on a glass slide.

RESULTS

Tissue preparation. Preparations of segments of normal (uninjured) aorta incubated in 4% RSA-MEM showed

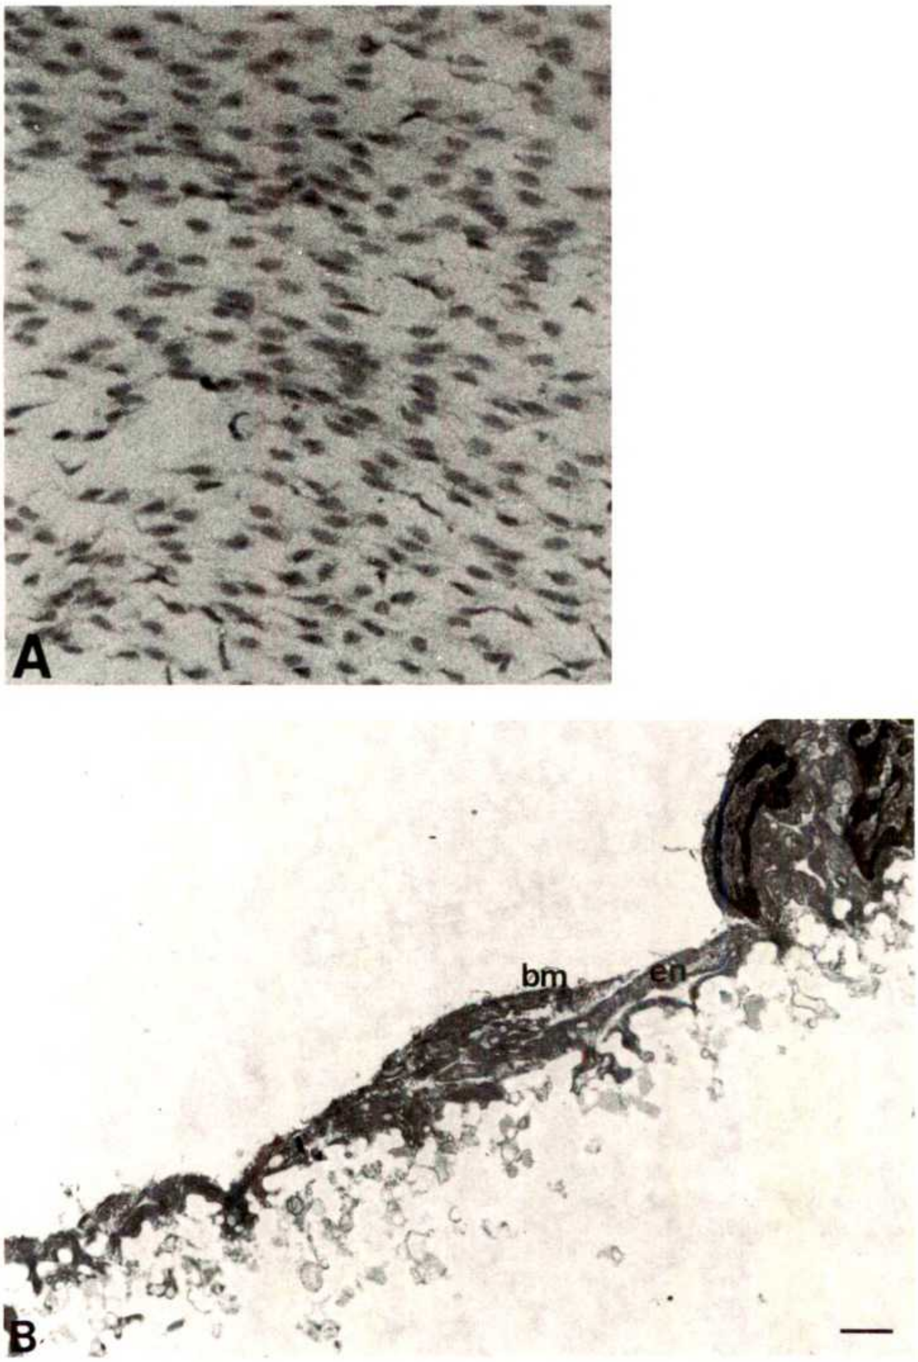

Fig 1. Morphologic examination of rabbit aorta endothelium and subendothelium after exposing the surface to cellulose acetate film. (A) Light micrograph of a toluidine blue–stained Hautchen preparation of endothelium. The endothelial cell layer is complete and indicates that most of the endothelial cell monolayer was removed by this technique (instrumental magnification × 100). (B) TEM of the endothelial cells attached to the cellulose acetate film. Only endothelial cells and remnants of basement membrane have been removed by the cellulose acetate film. Abbreviations: en, endothelial cell; bm, basement membrane; bar, l μ. (C) SEM of the subendothelial connective tissue exposed following cellulose acetate stripping of the endothelium. No remaining endothelial cells are evident. Instrumental magnification × 640 (bar, 100 μ); current magnification × 448.

that the endothelium was almost intact when examined by SEM and the cells showed minimal evidence of injury from examination by TEM. In segments from aortas that had been deendothelialized by balloon catheter the endothelium was completely removed, but remnants of intimal connective tissue remained above the internal elastic lamina. Light microscopy of the endothelium removed by cellulose acetate showed a continuous monolayer of endothelial cells (Fig 1A), and TEM of this preparation confirmed that the endothelial cells were removed with only remnants of the adhering basement membrane (Fig 1B). SEM of the surface exposed after removal of the endothelium confirmed that most of the endothelial cells had been removed, thus exposing the subendothelial connective tissue (Fig 1C).

Effects of radiolabeling on certain properties of antithrombin III. All purified samples of antithrombin III were isolated from plasma not more than six days before labeling. The labeled samples were rechromatographed on Sepharose-heparin to determine whether the labeling process had damaged the heparin-binding function of the protein (Fig 2).

Unlabeled antithrombin III was distributed into approximately 20% to 30% of the protein that was unbound by heparin and 70% to 80% that during gradient elution

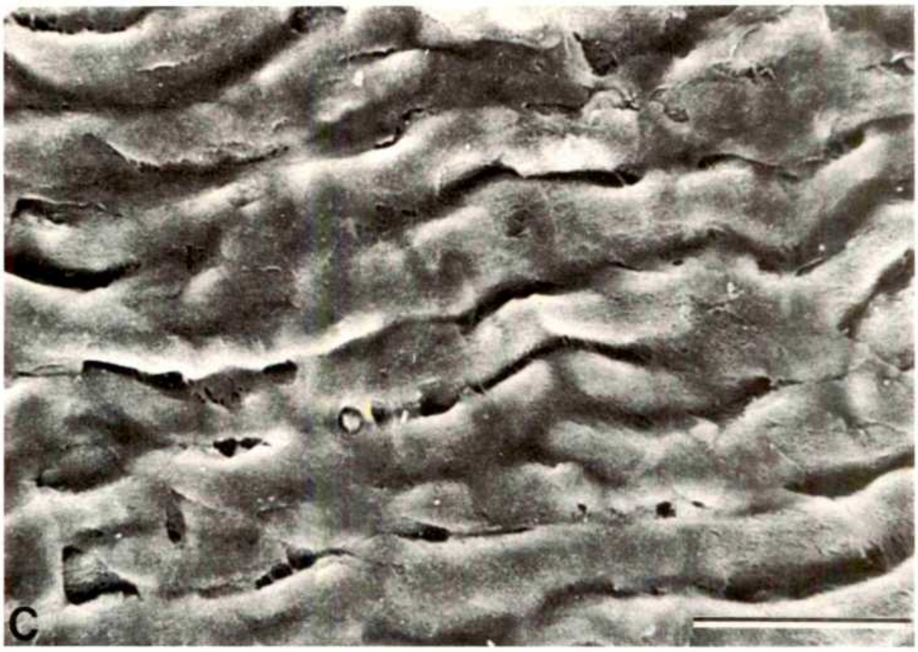

Fig 1. (Cont'd)

emerged as a sharp peak (Fig 2A). In contrast, 32% to 41% of the ^{125}I–antithrombin III passed through the affinity column, and 50% to 56% of the load was recovered during NaCl gradient elution as a double peak (Fig 2B). Of the ^{3}H–antithrombin III loaded, approximately 70% passed through the column, and only 20% to 23% was bound by and recovered from Sepharose-heparin. This fraction eluted as a sharp peak (Fig 2C), but considerably sooner than unlabeled antithrombin III.

Sephadex G-200 gel filtration did not reveal any significant differences between either labeled or unlabeled antithrombin III preparations (data not shown). Furthermore, neither iodination nor reductive methylation caused a decrease in the antithrombin activity of the protein. Indeed, reductive methylation slightly increased the antithrombin activity by approximately 4% to 16%.

Binding of antithrombin III to the aorta wall. Samples of ^{3}H- or ^{125}I-labeled antithrombin III were taken up rapidly by the endothelium at 37 °C; binding of either labeled antithrombin III reached a plateau within two minutes (Fig 3A and B). In contrast, uptake by the subendothelium (intima-media layer) of normal aorta segments was almost linear for at least 20 minutes. Compared to uptake experiments conducted using 4% RSA-MEM, uptake of ^{125}I–antithrombin III by the intima-medial layer in the presence of 5 mmol/L Na citrate was decreased by 20% to 35%. In contrast, endothelium uptake was not influenced by Na citrate.

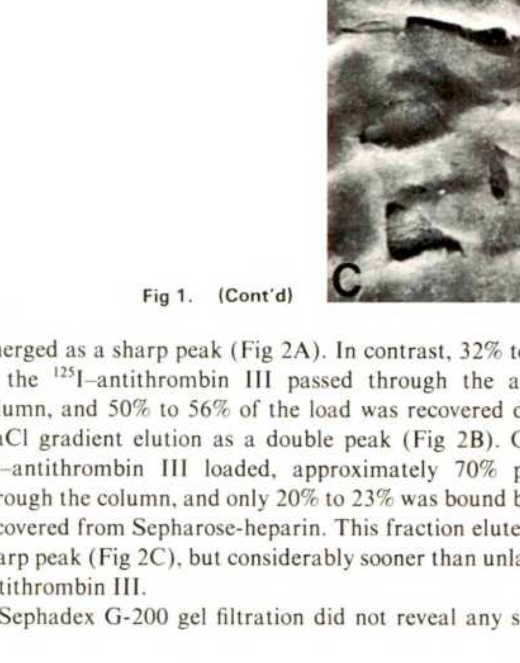

Fig 2. Chromatography of purified rabbit antithrombin III before and after radiolabeling on Sepharose-heparin (15 cm × 1.5 cm). (A) unlabeled, purified antithrombin III (approximately 3.5 mg), ●—● (B) ^{125}I–antithrombin III added to 100 mL of dialyzed supernatant from 50% saturated $(NH_4)_2SO_4$-treated rabbit plasma; absorbance (280 nm), □– – – –□; ^{125}I, ●—●. (C) ^{3}H–antithrombin III added to 100 mL of dialyzed supernatant from 50% $(NH_4)_2SO_4$-treated rabbit plasma; absorbance (280 nm), □– – – –□; ^{3}H, ●—●. After washing each column with 200 mL of the equilibration buffer (0.01 mol/L Na phosphate/0.15 mol/L NaCl, pH 7.3), the gradient (denoted by the arrow) was commenced: mixing chamber, 200 mL of equilibration buffer; limit solvent, 0.01 mol/L Na phosphate containing 1.5 mol/L NaCl). The fraction volume was 5 mL (ncpm, net count per minute).

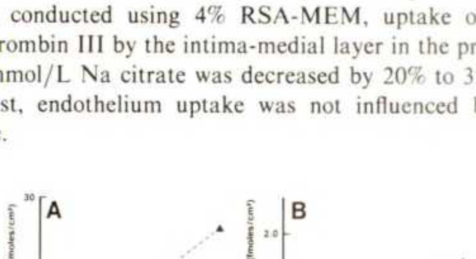

Fig 3. Uptake of radiolabeled antithrombin III by the luminal surface of normal aorta segments. (A) Segments were immersed in 1 mL 4% RSA-MEM containing ^{3}H–antithrombin III (42 pmol) for the times stated. After rinsing (one minute, 4 mL MEM), the vessel layers were stripped and counted. (B) Segments were placed in 1 mL 4% RSA-MEM containing ^{125}I–antithrombin III (1.3 pmol) and then treated as in (A). Antithrombin III was associated with both the endothelium (○—○) and subendothelium (intima-media) (▲—▲).

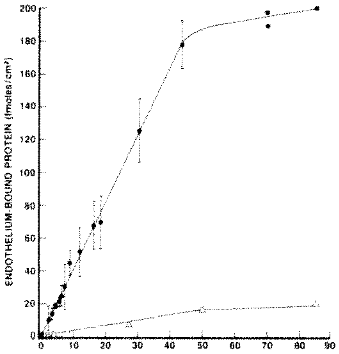

Fig 4. A comparison of binding of antithrombin III with binding of thrombin by the normal aorta endothelium. Aorta segments were placed for ten minutes in 1 mL 4% RSA (or BSA)-MEM containing up to 90 pmol of either thrombin (traced with ^{125}I-thrombin, ●—●) or antithrombin III (traced with either ^{125}I-antithrombin III, ○—○; or with ^{3}H-antithrombin III, △—△). After rinsing in MEM (one minute), the endothelial layer was stripped from each segment and counted. Thrombin results are given as the mean (± SD) where n = 6 to 11 aorta segments; each antithrombin III result is the average of two values.

Uptake of ^{125}I-antithrombin III (at a concentration of 1.3 to 3.2 pmol/mL) by the exposed intima-medial layer of deendothelialized (ballooned) segments during ten minutes (approximately 5.5 × 10^8 molecules/cm^2/min) was almost four times faster than that of ^{125}I-antithrombin III by the subendothelial layer of normal vessel segments (approximately 1.5 × 10^8 molecules/cm^2/min).

Comparison of uptake of antithrombin III with that of thrombin by the aorta endothelium. Each protein, in concentrations ranging from 1 to 60 pmol/mL, was incubated with intact aorta segments for ten minutes at 37 °C (Fig 4). These experimental conditions were assumed to allow equilibrium to be established between the endothelium-bound and free protein. Over the range of 10 to 60 pmol/mL, the uptake of thrombin by the endothelium was at least tenfold greater than the uptake of antithrombin III. The uptake of ^{3}H-antithrombin III did not appear to differ from that of ^{125}I-antithrombin III.

Effect of glycosaminoglycan-specific enzymes and heparin on the ability of the aorta wall to bind antithrombin III. Prior exposure of intact aorta segments to chondroitinase AC or chondroitinase ABC did not influence the uptake of ^{125}I-antithrombim III by either the endothelium or the underlying intima-media (Table 1). Heparitinase pretreatment did not affect uptake by the endothelium but did decrease uptake by the intima-media. Similar to the result with ^{125}I-antithrombin III, uptake of ^{3}H-antithrombin III was not significantly influenced by prior exposure of aorta segments to either chondroitinase AC or ABC. In comparison, the action of glycosaminoglycan-specific enzymes on the deendothelialized (ballooned) aorta segments caused a significant decrease in ^{125}I-antithrombin III uptake by the intima-medial layer. Indeed, heparitinase pretreatment reduced ^{125}I-antithrombin III to only approximately 20% of that of the control values.

Pretreatment of the normal vessel wall with heparin (10 U/mL) did not alter ^{125}I-antithrombin III uptake by either the endothelium or subendothelium. Furthermore, the quantity of endothelium-bound ^{125}I-antithrombin III displaced by either unlabeled antithrombin III, heparin, or thrombin was not significantly different from that displaced by 4% RSA-MEM (Table 2). However, ^{125}I-antithrombin III associated with the subendothelium of the normal vessel was actively displaced by either thrombin or heparin, and from the intimal surface of the ballooned vessel, by thrombin, heparin, or unlabeled antithrombin III.

Interaction between antithrombin III and thrombin at the normal vessel wall. In these experiments, either protein was labeled with ^{125}I radioactivity. When bound to the endothelium, ^{125}I-thrombin was rapidly displaced by placing the aorta segment in either purified antithrombin III or in defibrinogenated, recalcified rabbit plasma (Fig 5A): 50% of bound thrombin was displaced during five minutes (37 °C) by approximately 70 pmol of purified antithrombin III/mL of 4% RSA-MEM or by the equivalent of 35 pmol/mL of antithrombin III in recalcified plasma. The released radioactive products, when chromatographed on Sephadex G-200, gave similar elution profiles (Fig 5B and C). The products were of substantially greater molecular weight than either

Table 1. Effect of Pretreatment of Normal and Ballooned Aorta Segments With Various Agents on the Uptake of ^{125}I-Antithrombin III

Pretreatment		Percentage of ^{125}I-Antithrombin III Bound by		
		Normal Aorta		Ballooned
Reagent	Time (min)	Endothelium	Intima-Media	Intima-Media
4% BSA-MEM	5–10	100	100	100
Chondroitinase AC (5 IU/mL)	10	106	90	78
Chondroitinase ABC (5 IU/mL)	10	100	97	75
Heparitinase (5 IU/mL)	10	101	66	23
Heparin (10 U/mL)	5	114	86	—
Thrombin* (133 IU/mL)	10	101	73	—
Thrombin† (133 IU/mL)	10	142	109	—

Aorta segments were incubated for five or ten minutes in 1 mL of MEM containing BSA or RSA (4% wt/vol) and the reagent. The segments were rinsed (4 mL MEM, one minute) and then placed in ^{125}I-antithrombin III (usually 1.4 to 3.2 pmol, but see asterisks) in 1 mL of 4% BSA or RSA-MEM for ten minutes. The segments were rinsed (4 mL MEM, one minute), and then the layers of aorta wall, ie, the endothelium and the deendothelialized intima-media, were separated and the bound radioactivity measured. Control (ie, treatment with BSA or RSA-MEM alone) and test segments were always taken from the same aorta; mean results from test segments (n = 2 to 4) are compared to those from adjacent control segments and expressed as a percentage of bound radioactivity. For the two thrombin experiments, different antithrombin III concentrations were used: *1.4 pmol/mL, †0.14 pmol/mL.

Table 2. Displacement of ^{125}I–Antithrombin III Bound to the Normal and Ballooned Aorta Wall

Displacement		Percentage of ^{125}I–Antithrombin III Bound by		
		Normal Aorta		Ballooned Aorta
Reagent	Time (min)	Endothelium	Intima-Media	Intima-Media
None	—	100	100	100
MEM	5	64.1	61.2	—
4% RSA-MEM	2	55.5 ± 5.2	73.1 ± 15.4	—
4% RSA-MEM	5	45.9 ± 8.8	57.8 ± 9.4	83.2 ± 8.5
4% RSA-MEM	10	47.7 ± 9.4	57.5 ± 6.9	68.4 ± 7.7
Heparin (10 U/mL)	5	50.2 ± 6.2	37.1 ± 4.3	—
Heparin (10 U/mL)	10	—	—	28.3 ± 7.5
Antithrombin III (794 pmol/mL)	5	40.9 ± 7.8	55.2 ± 8.2	53.1 ± 7.0
Thrombin (67 IU/mL)	5	44.5	25.2	15.7 ± 5.9

Aorta segments were incubated in 1 mL 4% RSA-MEM containing ^{125}I–antithrombin III (1.6 to 3.2 pmol) for 10 minutes. After rinsing (4 mL MEM, one minute), the segments were exposed to various treatments to measure the displacement of bound ^{125}I–antithrombin III from the luminal surface of the vessel wall. As in Table 1, the endothelium and the deendothelialized intima-media were separated from the wall before counting; test and control (ie, no posttreatment) segments were taken from the same aorta, and results from test segments are expressed as a percentage (±SD, n = 4 to 8) of the bound radioactivity of the control results.

^{125}I–antithrombin III (Fig 5B) or ^{125}I-thrombin (Fig 5C) and, therefore, were presumed to contain thrombin–antithrombin III complexes.

DISCUSSION

Using an in vitro technique, we have shown that the capacity of the endothelium of the rabbit aorta for binding antithrombin III was considerably less than the capacity for binding either rabbit[13] or bovine thrombin at similar protein concentrations. Furthermore, unlike the endothelial binding sites for thrombin,[13,18] those for antithrombin III were not sensitive to glycosaminoglycan-degrading enzymes, and heparin pretreatment did not greatly influence the binding of ^{125}I–antithrombin III. Also, unfractionated ^{3}H–antithrombin III, which was shown to have a decreased affinity to Sepharose-heparin (Fig 2C) (due probably to *N*-methylation of the lysyl residues essential for heparin binding[1]), did not differ in its endothelium binding properties from that of unfractionated ^{125}I–antithrombin III (compare Figs 3A and 3B). Furthermore, uptake of unfractionated ^{125}I–antithrombin III by the aorta endothelium resembled that of the Sepharose-heparin–bound fraction of ^{125}I–antithrombin III.[18] Lastly, endothelium-bound antithrombin III, in contrast to endothelium-bound thrombin,[13] was not rapidly displaced by heparin. From these data we conclude that luminal binding sites for antithrombin III are relatively few in the normal aorta and that they are not of a proteoglycan nature. This conclusion is supported by the finding that pretreatment of the intact vessel segment with either purified antithrombin III or defibrinogenated plasma did not impede uptake of ^{125}I-thrombin or cause rapid formation of a ^{125}I-thrombin–antithrombin complex.[18] Also, our data compare well with those of Bauer et al[19] who compared the binding of ^{125}I–antithrombin III and ^{125}I-thrombin to cultured bovine endothelial cells.

In contrast to the endothelium, binding of ^{125}I–antithrombin III by the subendothelium of the intact aorta was rapid and nonsaturable over the time period of our experiments. The transendothelial uptake probably resulted from intercellular passage in a manner similar to that for ^{125}I-thrombin.[22] Thus, removal of the endothelium, ie, balloon catheter treatment, allowed the rate of uptake of ^{125}I–antithrombin III to increase substantially. Pretreatment of the deendothelialized (ballooned) surface with either chondroitinase AC, ABC, or, particularly, heparitinase decreased significantly the ^{125}I–antithrombin III uptake compared with the untreated, deendothelialized controls. Also, heparin actively displaced ^{125}I–antithrombin III from the deendothelialized vessel surface. We conclude that subendothelial glycosaminoglycans, particularly heparan sulphate, are responsible for much, if not all, of the ^{125}I-antithrombin binding in this region. This conclusion is supported by the observation that the Sepharose-heparin–bound fraction of ^{125}I–antithrombin III was bound three times more avidly by the deendothelialized (ballooned) intima-media than the unbound fraction (Hatton and Moar, unpublished results).

The significance of ^{125}I–antithrombin III uptake by the subendothelial layer of the intact aorta in vitro is not fully understood. Possibly, such an uptake indicates a compromised vessel surface that, lacking a normal, pressured blood flow, has relaxed, and the endothelial cells, instead of maintaining a flattened, plasma-tight surface, have become artificially parted from each other. The resulting intercellular gaps may encourage passage of certain proteins, particularly proteins with affinities to subendothelial constituents.

A portion (50% to 60%) of the antithrombin III bound to the endothelial surface of the vessel wall was readily displaced when incubated with 4% RSA-MEM (Table 2). Possibly, binding to the vessel wall may have resulted in endocytosis of the remainder of the antithrombin III. Neither heparin nor thrombin were able to dislodge more than 60% of the bound ^{125}I–antithrombin III (Table 2). The apparently poor reaction between endothelium-bound antithrombin III and thrombin may be explained by the following: (1) the quantity of displaceable antithrombin III bound to the endothelium is negligible; and (2) antithrombin III is bound at sites that are not of a glycosaminoglycan nature, and therefore, contact between bound antithrombin III and bound thrombin is unlikely. Thus, rather than antithrombin III binding to and becoming activated by pericellular proteo-

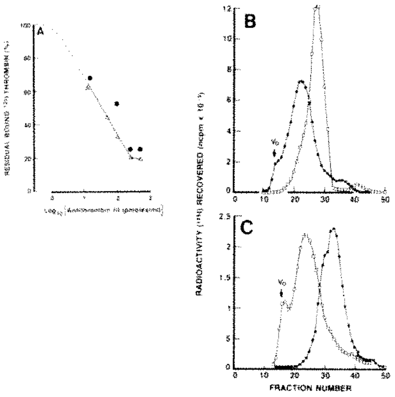

Fig 5. Displacement of ^{125}I-thrombin bound to the endothelium of intact aorta by either purified antithrombin III or defibrinogenated, recalcified rabbit plasma. (A) Aorta segments were exposed for ten minutes to ^{125}I-thrombin (1.7 to 5.3 pmol) in 1 mL 4% RSA-MEM; after washing in MEM (one minute), segments (containing 36.1 ± 21.2 femtomoles/cm^2 of endothelium) were placed for five minutes in either 1 mL 4% RSA-MEM containing antithrombin III, 1 mL of defibrinogenated plasma (diluted as necessary with MEM), or 1 mL of 4% RSA-MEM. The quantity of endothelium-bound ^{125}I-thrombin, after exposure to each antithrombin III concentration, is calculated as a percentage of the quantity of endothelium-bound ^{125}I-thrombin contained by adjacent aorta segments that had been exposed to 4% RSA-MEM only. Thus, ^{125}I-thrombin was displaced by purified antithrombin III (●) and by defibrinogenated plasma (Δ). The slope is extrapolated to the 100% value that represents the quantity of endothelium-bound ^{125}I-thrombin contained by control segments exposed to 4% RSA-MEM only. (B) Sephadex G-200 chromatography (58 cm × 1 cm) of the displaced products (●—●) obtained when aorta-bound, unlabeled thrombin (1-cm aorta segment exposed to 2,083 pmol of thrombin for ten minutes and then rinsed for one minute) was reacted with ^{125}I–antithrombin III (0.13 pmol) for five minutes. The radioactive products are compared with ^{125}I–antithrombin III (□—□) that was exposed to aorta that had been pretreated with 4% RSA-MEM only. (C) Sephadex G-200 (58 cm × 1 cm) elution profile of the soluble radioactive products (□—□) recovered from the interaction between aorta-bound ^{125}I-thrombin (1-cm aorta segment exposed to 0.2 μg of ^{125}I-thrombin for ten minutes and then rinsed for one minute) that had been exposed to Arvin-treated, recalcified rabbit plasma for two minutes. For comparison, ^{125}I-thrombin added to 150 IU of unlabeled purified thrombin as a carrier was chromatographed on a Sephadex G-200 column of similar dimensions (●—●).

glycan of the endothelium, a more likely anticoagulant property of the aorta endothelium stems from thrombin binding to proteoglycan and thus reacting with plasma antithrombin III.

Vessel wall–bound thrombin was rapidly displaced by antithrombin III or by defibrinogenated plasma (Fig 5A) to yield thrombin–antithrombin III complexes (Figs 5B and C).[16,18,22] The elution profile of the ^{125}I-thrombin–antithrombin III (Fig 5C) was similar to that of thrombin–^{125}I-antithrombin III (Fig 5B). Presumably, α-2-macroglobulin did not play a major part in thrombin inhibition by the defibrinogenated, recalcified plasma or a proportionately greater 19S peak would have been observed in Fig 5C as compared with 5B. However, we do not rule out the possibility of thrombin inhibition by other plasma protease inhibitors, eg, heparin cofactor II.[31]

Our observations on the relationship between antithrombin III and the endothelium contrast with other reports. Busch and Owen,[32] using both Langendorff heart preparations and cultured endothelial cells, concluded that the endothelium contained a surface cofactor, which was probably a proteoheparan sulphate, for binding antithrombin III. No direct measurement of antithrombin III binding was reported, and much of the evidence for a proteoglycan-containing binding site came from experiments using protamine and diisopropyl fluorophosphate (DFP)–thrombin as inhibitors of the heparin–antithrombin III and thrombin–antithrombin III reactions, respectively. However, these agents will also inhibit thrombin binding to the endothelium.[15,16,22] Marcum et al[4] have isolated a heparinlike anticoagulant from an endothelial cell fraction prepared from the miscrovasculature of calf retina. This glycosaminoglycan preparation was shown to bind to Sepharose–concanavalin A–immobilized antithrombin III and be displaced by 1 mol/L NaCl, but no mention was made whether thrombin would also bind to this fraction. The anticoagulant activity was destroyed by a purified heparinase preparation. More recently Marcum et al[3] demonstrated that perfusion of the microvasculature of the rat hind limb with heparinase destroyed the property that enhanced the rate of thrombin inactivation by antithrombin III. Perfusion of DFP-thrombin reduced the amount of the thrombin–antithrombin III complex formed by 30% to 40%, which confirmed earlier observations of Lollar and Owen.[15] These latter authors proposed that thrombin binding to the endothelium was a necessary step toward thrombin inactivation by antithrombin III.

The recent study by Stern et al[17] of bovine antithrombin III binding by bovine aorta segments would appear to contradict our observations on the rabbit aorta. However, the solvation technique used by Stern et al to quantitate the ^{125}I–antithrombin III bound to the endothelium differs significantly from the Hautchen technique[29] used in our study. In a preliminary investigation to compare these two procedures, we determined that the solvent (0.2 mol/L NaOH, 1% SDS, 0.01 mol/L EDTA) used by Stern et al dissociated 26% of the bound ^{125}I–antithrombin III from the endothelium and 54% from the underlying intima-media of normal rabbit aorta segments. We believe, therefore, that the relatively high values of ^{125}I–antithrombin III bound to the luminal surface that were reported by Stern et al are due to measurement of the ^{125}I–antithrombin III displaced from the endothelium and subendothelium, whereas with our procedure, endothelium-bound antithrombin III is sharply separated from that of the subendothelial compartment (Fig 1).

Possibly the endothelial cells of the microcirculation possess pericellular proteoglycans that act as binding sites for attracting antithrombin III and thrombin to catalyze thrombin inactivation. In contrast, the endothelial cells of the aorta attract only thrombin through proteoglycan-containing binding sites, and inactivation of endothelium-bound thrombin is performed by plasma antithrombin III. These two cellular mechanisms may have evolved to reflect different blood flow conditions. The microvasculature is comprised of 95% of the total vascular surface area but contains only 5% of the entire blood volume, which moves comparatively slowly (0.07 cm/s).

The arterial system contains <1% of the vascular surface area and transports approximately 20% of the blood at 40 to 50 cm/s.[33]

Finally, the presence of a significant pool of antithrombin III at the vessel wall is also supported by catabolic[34] and histologic studies,[35] although the histologic investigation of human blood vessels by Becker and Harpel[36] did not detect antithrombin III on the endothelial cell lining. However, if such a pool does exist, contained by pericellular heparinlike proteoglycan of the endothelium, then infusion of heparin would presumably displace this bound antithrombin III into the lumen, and a rapid rise in circulating anthithrombin III should be observed. To our knowledge, a heparin-stimulated increase in antithrombin III level has not been recorded; indeed, intravenous heparin therapy generally causes a decrease in antithrombin III levels in patients,[37-39] resulting probably from increased protein turnover.[40]

ACKNOWLEDGMENT

We thank Dr Jack Gauldie (Department of Pathology, McMaster University Health Sciences Centre) for kindly supplying the antiserum to rabbit antithrombin III.

Ionic Strength Dependence of the Polymer Solubilities of Deoxyhemoglobin S + C and S + A Mixtures

By Robert M. Bookchin and Tania Balazs

Factors contributing to the clinical differences between sickle cell–hemoglobin C disease (SC) and the benign sickle cell trait (AS) include the higher proportion of hemoglobin (Hb) S and the higher cell Hb concentrations in SC compared with AS red cells. Reports differ, however, about whether Hb C copolymerizes more than Hb A with Hb S when measured by minimum gelling concentrations (MGCs) and polymer solubilities of the deoxy-Hb mixtures. We now show that the MGCs and solubilities of equimolar mixtures of Hb S + Hb C vary much more with the ionic strength (μ) of the solution than those of Hb S + Hb A mixtures. At $\mu \leq 0.20$, but not at $\mu > 0.25$, Hb S + Hb C solubilities were significantly lower than those of Hb S + Hb A. These differences, which may reflect a greater effect of the β^6Lys$^+$ in Hb C at lower μ, can account for the reported discrepancies. The solubility differences were similar in the presence or absence of asymmetric hybrids, and since the intratetramerically cross-linked hybrids $\alpha_2\beta^s\beta^A$ and $\alpha_2\beta^s\beta^c$ had similar solubilities, they did not indicate the usual mechanism, involving greater incorporation of $\alpha_2\beta^s\beta^c$ into the polymers. The small solubility differences between the two Hb mixtures at physiologic (red cell) concentrations of Hb and 2,3-diphosphoglycerate probably play a minor role in the clinical differences between SC and AS states.

© 1986 by Grune & Stratton, Inc.

SICKLE CELL–hemoglobin C disease (SC) is characterized by an overall clinical severity, in terms of the anemia and vasoocclusive episodes, that is intermediate between the severe homozygous sickle cell anemia (SS) and the essentially benign sickle cell trait (AS). Although earlier measurements of the minimum gelling concentrations (MGC) of hemoglobin (Hb) S-C mixtures[1-3] suggested that the major cause of the increased severity of SC disease, compared with AS, was a greater tendency of Hb C to copolymerize with Hb S, recent reports[4,5] have pointed out two other important factors contributing to SC severity—a larger proportion of Hb S in SC than in AS red cells and an increased intracellular Hb concentration in the SC cells. In one of these studies,[5] detailed measurements of polymer solubilities and the kinetics of polymerization showed no significant differences between comparable mixtures of Hb S + C and Hb S + A. No explanation was provided, however, for the apparent discrepancy between these results and the earlier MGC studies. A review of these different reports revealed that the solubility or MGC measurements were made in media whose ionic strength and composition varied considerably from one study to another. Since Hb C differs from Hb A by the substitution of the charged amino acid residue Lys$^+$ for the normal β6Glu$^-$, it seemed likely that any differences in the behavior of Hb C from Hb A would be dependent on ionic strength, ie, they would be minimized in relatively high ionic strength media that would shield the β6Lys$^+$ charge of Hb C. We therefore undertook a study of the ionic strength dependence of the MGCs and polymer solubilities of Hb S + A and Hb S + C mixtures.

Since the aforementioned studies also differed in the starting total concentration of Hb, which might itself affect the ionic strength of the mixtures, we also tested the effects on solubility of high initial total Hb concentration, as well as the effects of physiologic (red cell) levels of 2,3-diphosphoglycerate (2,3-DPG).

As will be discussed further, the location of the substitution in Hb C, which is the same as that in Hb S (β6) predicts that the β6 lysine residue in $\alpha_2\beta^s\beta^c$ asymmetric hybrid tetramers should not be in an intermolecular contact area of the Hb S polymer.[6,7] We therefore examined the role of $\alpha_2\beta^s\beta^c$ hybrids in polymerization by comparing the polymer solubilities of the nondissociable, intramolecularly cross-linked hybrid tetramers[8] $\alpha_2\beta^s\beta^c$, $\alpha_2\beta^s\beta^A$, and $\alpha_2\beta^s_2$. In addition, we compared the solubilities of Hb S + C mixtures in which hybrid formation was either permitted or prevented by deoxygenation of the non-S Hb prior to mixing.

MATERIALS AND METHODS

Fresh heparinized blood was obtained, with informed consent, from donors established to be homozygous for Hb S (SS) or for Hb C (CC) by electrophoretic and family studies at our Heredity Clinic and from normal (AA) donors. SS and CC donors were chosen in whom the proportion of Hb F in the red cell hemolysates, as measured by alkali denaturation,[9] was 2% or less. Hemolysates were prepared by the method of Drabkin,[10] and Hb concentrations were measured by the cyanmethemoglobin method.

Preparation of Hb solutions and mixtures. In some experiments Hb S was separated from the minor components Hb A_2 and Hb F by chromatography on columns of microgranular diethylaminoethyl (DEAE)-cellulose (DE-52, Whatman), developed with 0.05 mol/L Tris-HCl, pH 8.1. Since the MGC and solubility results obtained using the purified Hb S did not differ significantly from those using unchromatographed, low-Hb F-hemolysates, subsequent experiments used the latter preparations. Since Hb A_2 cannot be readily separated from Hb C on a large scale[11] and attempts to isolate Hb C from AC or SC hemolysates would substantially enrich the proportion of Hb A_2 in the Hb C fraction with possible unintended effects on the solubilities,[12] CC hemolysates were used without further purification. Accordingly, for comparison no measures were taken to purify AA hemolysates. All hemolysates were dialyzed overnight at 4 °C against K-phosphate buffer (pH 7.35) between 0.025 and 0.15 mol/L. To maximize the accuracy of mixing equimolar quantities of Hb S + A or Hb S + C, in the majority of solubility experiments in which the Hbs were mixed in the oxygenated form, exact volumes of relatively dilute Hb solutions of measured concentration (about 10 g Hb/dL) were mixed prior to vacuum ultrafiltration and continued dialysis overnight against the appropriate buffers. The concentrated

Hb mixtures were diluted with the same buffer to the desired starting total Hb concentrations. To avoid any possible effects of minor differences in Hb S hemolysates when comparing the MGCs and solubilities, each experiment compared Hb S + A and Hb S + C mixtures, each made in duplicate using the same Hb S solution.

Measurements of MGC and Polymer Solubilities. These procedures followed methods previously described.[8,13] Briefly, approximately 0.6 mL of Hb mixtures of measured starting total Hb concentrations were placed in 10-mL Ehrlenmeyer flasks and equilibrated for 30 to 40 minutes with water-equilibrated N_2 gas at 23 °C or in a warm room at 37 °C. The closed flask was briefly chilled on ice and, following anaerobic addition of a small volume of a deoxygenated solution of sodium dithionite in 0.001 mol/L NaOH to a final concentration of 1 mol/mol Hb tetramer, was rewarmed and the gas switched to dry N_2 to permit the Hb concentration to rise slowly by evaporation. The sample was chilled every few minutes to fully liquefy the thickening deoxyhemoglobin and to ensure complete mixing and rewarmed. Once a firm gel had formed, it was again chilled to liquefy it and, using a gas-tight syringe flushed with N_2 gas, transferred anaerobically to a cellulose nitrate tube under oil. A small aliquot was placed in a separate tube for measurements of Hb concentration (MGC). The centrifuge tubes were temperature equilibrated for 30 minutes and spun at 23 °C or 37 °C for 120 minutes at 122,000 g in a Beckman L3-50 centrifuge (Beckman Instruments, Inc, Fullerton, Calif) using an SW65K rotor to sediment the solid phase. The supernatants were fully decanted and aspirated into a separate tube and mixed completely before measuring the Hb concentration in triplicate, and the pH, using a glass microcapillary gun electrode (Radiometer, model E5021a Copenhagen), equilibrated at 23 °C or 37 °C. The ionic strengths of the phosphate buffer components were obtained using the nomogram of Boyd,[14] taking into account the final pH of the supernatants and, from the MGC values of total Hb concentration compared with the starting values, the effect of evaporation on the concentrations. The ionic strength of the sodium dithionite was calculated using the formula $\mu = \Sigma C_i Z_i^2/2$, where C_i is the molar concentration of each ionic component and Z_i its valency. To measure both the MGCs and solubilities on the same Hb solutions in these experiments for comparison with some of the earlier studies, the starting Hb concentrations were chosen to be about 1 g Hb/dL below the predicted MGCs; if gelation occurred either before dry N_2 gas was used or if the MGC exceeded the starting Hb concentration by more than 6%, the experiments were repeated starting with lower or higher total Hb concentrations, respectively.

In the experiments testing the effect on polymer solubility of initial Hb concentrations comparable to those in the red cell, it was not possible to measure MGCs, but otherwise the techniques just described were used. To test the effect of addition of 2,3-DPG, the Hb samples were dialyzed against 0.05 mol/L bis-Tris buffer, pH 7.35, containing 0.1 mol/L KCl (for controls without 2,3-DPG) or 0.08 mol/L KCl (for samples to which 2,3-DPG was added) so as to keep the final ionic strength similar. 2,3-DPG was added in solid form since the free acid (obtained by passing the pentacyclohexylammonium salt over Dowex 50 resin [Sigma Chemical Co, St Louis]) titrated to pH 7.0 with 0.1 N NaOH), thus giving a final concentration of 1 mol 2,3-DPG per mole Hb tetramer. An attempt was made to use a CO_2-bicarbonate buffer system instead of bis-Tris buffer, but in this system it was not possible to maintain equal final pH values in Hb S + C and Hb S + A solutions run simultaneously.

To prevent hybrid tetramer formation in Hb mixtures used to measure the MGC and polymer solubility, we followed a previously described[15] procedure based on the very small dissociation of deoxyhemoglobin tetramers into dimers. The non-S Hb (Hb A or Hb C) was deoxygenated in one flask, whereas the Hb S, which had been converted into the cyanmet-form to prevent gelation, was equilibrated with N_2 gas in another flask. An appropriate volume of the oxygen-free cyanmet-Hb S was then transferred anaerobically to the deoxygenated non-S Hb solution to achieve equimolar Hb quantities in the mixture, and after chilling and thorough mixing, the cyanmet-Hb was reduced to the deoxy-form by anaerobic addition of 1 mol sodium dithionite per mole cyanmetheme plus 1 mol dithionite per mole Hb tetramer. Parallel experiments were always done in which the Hb S and non-S Hb were mixed in the oxy-forms and the same additional amount of dithionite was added. The MGCs and polymer solubilities were then determined as previously noted. For these experiments, all Hb components were dialyzed and concentrated separately against 0.05 mol/L K-phosphate buffer, pH 7.35.

Preparation of cross-linked asymmetric hybrids. These preparations followed the methods of Macleod and Hill,[15] as described previously.[8,16] Equimolar mixtures of Hb S with either Hb C or Hb A in the CO-form were each reacted with the bifunctional cross-linking reagent difluoroditrophenylsulfone (FNPS), and the cross-linked tetramers were separated from unreacted Hb by chromatography on Sephadex G-100 (Pharmacia Fine Chemicals, Piscataway, NJ) in 1 mol/L $MgCl_2$. Two of the three major components separated on preparative isoelectric focusing beds, representing cross-linked $\alpha_2\beta_2^s$ and either $\alpha_2\beta^A\beta^s$ or $\alpha_2\beta^s\beta^c$, primarily cross-linked between the NH_2 termini of the α chains,[15] were isolated, and stored in the CO-form as frozen beads in liquid N_2 until sufficient material was accumulated for solubility experiments. Then each was converted to the cyanmet-form to permit rapid conversion to the deoxy-form with dithionite, dialyzed, and concentrated against 0.05 mol/L K-phosphate buffer. The MGC and solubilities were measured as previously described except that the amount of dithionite added was 4.25 mole per mole Hb tetramer to provide an excess over the amount needed for reduction of the cyanmet-Hb.

RESULTS

Effect of ionic strength variations on solubilities of deoxyhemoglobins S + A and S + C. The polymer solubilities of equimolar mixtures of the deoxyhemoglobins S + A and S + C at 37 °C and 23 °C are shown in Fig 1. Although the ionic strength dependence of the solubilities of both mixtures was slightly greater at 23 °C than at 37 °C, the overall changes were similar at both temperatures, with Hb S + C mixtures showing a much larger ionic strength dependence than the Hb S + A mixtures. Although there was little or no solubility difference between the two mixtures in the higher ionic strength range, $\mu = 0.25$ to 0.40 (which includes the condition in 0.15 mol/L K-phosphate buffer), the Hb S + C mixtures were considerably less soluble than Hb S + A mixtures at ionic strengths below 0.20. Thus, in the ionic strength range 0.12 to 0.14 at 37 °C, the solubility of Hb S + A (26.8 g Hb/dL) was about 9% greater than that of Hb S + C (24.6 g Hb/dL).

In each of the experiments shown in Fig 1, MGC values were obtained following gelation of the Hb mixture prior to centrifugation. The Hb concentrations representing the MGCs (not shown) were consistently between 5% and 10% higher than the corresponding solubilities, as measured by the supernatant Hb concentrations after centrifugation. The patterns of change with ionic strength for Hb S + A and Hb S + C mixtures at both 25 °C and 37 °C were thus the same when comparing the MGCs as they were with solubilities.

Effects of high-Hb concentrations and 2,3-DPG on solubilities. Because of the possibility that Hb itself could contribute significantly to the total ionic strength inside red

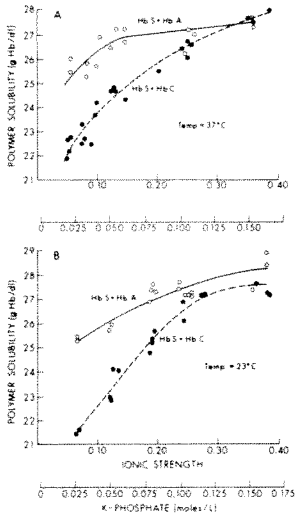

Fig 1. Effect of ionic strength variation on the polymer solubility of equimolar mixtures of Hb S + Hb A and of Hb S + Hb C. Each point represents the average of duplicate measurements using the same Hb mixtures, which differed from each other by 0.5 g Hb/dL or less. The final pH of the supernatant Hb solutions after centrifugation was 7.0 to 7.1. The ionic strengths of the solutions were calculated as described in Materials and Methods, taking into account the effects of evaporation on the final phosphate concentrations and the contribution of the sodium dithionite added. (A) 37 °C. (B) 23 °C.

cells (H.F. Bunn, personal communication), additional solubility measurements were made comparing deoxyhemoglobins S + A and S + C with initial total Hb concentrations comparable to those in the red cell, 34 g Hb/dL. In addition, the possible effects of the allosteric ligand 2,3-DPG were tested. The results (Table 1) indicate that the solubility differences between Hb S + A and Hb S + C are considerably smaller at these higher starting Hb concentrations than at initial Hb concentrations close to the MGC values. Solubilities in bis-Tris–KCl were similar to those in 0.05 mol/L phosphate buffer, but upon addition of 2,3-DPG, the differences between Hb S + A and Hb S + C were further reduced, although still statistically significant.

Table 1. Polymer Solubility of Hb S + A and Hb S + C Mixtures at Hb Concentrations Found in Red Cells

Buffer Condition	Solubility* (g Hb/dL) S + A	Solubility* (g Hb/dL) S + C	Mean Difference and Significance†
0.05 mol/L K-phosphate	32.83 ± 0.35	31.05 ± 0.36	1.78 ± 0.05 $P < .001$
0.05 mol/L bis-Tris 0.1 mol/L KCl	32.60 ± 0.16	31.17 ± 0.17	1.43 ± 0.06 $P < .001$
0.05 mol/L bis-Tris 0.08 mol/L KCl 5.0 mmol/L 2,3-DPG	32.87 ± 0.09	31.80 ± 0.14	1.07 ± 0.29 $P < .05$

*Each solubility value represents the mean ± SD of three or four paired samples in which Hb A or Hb C was mixed with the same solution of Hb S.

†Paired *t* statistic.

Starting total Hb concentrations were 34.0 g Hb/dL. All mixtures received, in addition, 1 mol sodium dithionite per mole Hb tetramer after equilibration with N_2 gas.

Table 2. Effect of Asymmetric Hybrid Tetramers on the MGC and Polymer Solubility of Hb Mixtures

Hb Components (Equimolar)	Hybrids Present MGC*	Hybrids Present Solubility*	Hybrids Absent MGC*	Hybrids Absent Solubility*
Hb S + Hb A	29.8	27.4	30.3	28.1
Hb S + Hb C	26.2	24.8	26.6	25.0

*g Hb/dL.

Each value represents the mean of a duplicate determination; duplicates differed by less than 0.5 g Hb/dL. The same solutions of Hb S, Hb C, and Hb A were used for these experiments.

Hemoglobins were dialyzed against 0.05 mol/L K-phosphate and mixed in the oxy-form for hybrid formation or deoxy- + cyanmet-forms to prevent hybrids prior to the addition of sodium dithionite, as noted in Materials and Methods.

Measurements were made at 23 °C. Final pHs of supernatants were 7.0 to 7.1.

Effects of asymmetric hybrid tetramers. To test the possible role of asymmetric hybrid tetramers (such as $\alpha_2\beta^s\beta^c$) on the solubility differences between Hb S + C and Hb S + A mixtures, we compared their MGCs and solubilities under conditions in which hybrid formation was permitted, by mixing the oxyhemoglobins prior to deoxygenation, or was prevented by maintaining the non-S Hb in the deoxy-state during mixing. The results, in Table 2, show that the solubility of Hb S + C, like that of Hb S + A, as reported previously,[16,17] showed no significant difference in the presence or absence of hybrids and that the lower solubility of the Hb S + C mixture did not depend on hybrid tetramer formation.

In addition, the solubilities of the hybrid tetramers $\alpha_2\beta^s\beta^c$ and $\alpha_2\beta^s\beta^A$ were compared directly, using the purified components cross-linked intratetramerically between their α chains to prevent dissociation. As shown in Table 3, under conditions in which the solubilities of Hb S + C mixtures were considerably lower than Hb S + A mixtures, the cross-linked hybrids $\alpha_2\beta^s\beta^c$ and $\alpha_2\beta^s\beta^A$ showed no significant differences in MGC or solubility.

DISCUSSION

The main findings of the present study are first, the observed larger ionic strength dependence of the solubility of

deoxy-Hb S + C mixtures, compared with Hb S + A mixtures, explains the discrepancies in various reports about the behavior of the two mixtures. Secondly, under conditions mimicking the ionic strength and Hb concentrations within the red cell, the solubility of equimolar Hb S + C mixtures is only slightly lower than that of comparable mixtures of Hb S + A, substantiating the major conclusions of Bunn et al[5] that solubility differences between the two mixtures play no (or only a small) role in the clinical differences between AS and SC states. Thirdly, the solubility behavior of the asymmetric hybrids $\alpha_2\beta^s\beta^A$ and $\alpha_2\beta^s\beta^c$ are the same and are not the basis for the lower solubility of the Hb S + C mixtures at ionic strengths below 0.20.

Under conditions in which the gelation properties of deoxy-Hb S were commonly measured in phosphate buffers we find that both the solubilities and MGC values of equimolar mixtures of Hb S + C vary much more with the ionic strength of the media than do mixtures of Hb S + A. At ionic strengths below 0.20, the differences in MGC and solubility between the two Hb mixtures was fairly large, both at room temperature (23 °C) and at 37 °C, whereas the solubility differences disappeared at ionic strengths between 0.25 and 0.40. These findings can account for the discrepancies between earlier reports that the MGCs of Hb S + C mixtures were much lower than those of Hb S + A mixtures[1,2,3] and the recent report showing no differences.[5] Singer and Singer[1] made their measurements of MGC on undialyzed hemolysates diluted with distilled water or with buffers (whose concentrations were not described) and deoxygenated them with CO_2 gas. It is likely that the final solutions had a relatively low ionic strength as well as a relatively low pH. These investigators found the MGC values for Hb S + A mixtures from 12% to 20% higher than those of comparable Hb S + A mixtures. Allison,[2] who tested mixtures of Hb S + A and Hb S + C dialyzed against phosphate buffers, pH 7.35, ionic strength, 0.15 (equivalent to about 0.065 mol/L K-phosphate), also found both the MGCs and the minimum deoxy-Hb concentrations needed for a significant viscosity increment higher for the Hb S + A than for the Hb S + C mixtures. The results of Charache and Conley[3] are not easily compared with others since they studied the native hemolysates in which the proportion of HbS was 48% to 57% of the total Hb in the SC hemolysates and 34% to 41% in the AS hemolysates. Nevertheless, the large differences in the MGC values, 50% higher for the AS hemolysates, do not seem attributable only to the higher proportion of HbS in the SC cells and may be related to the way the solutions were prepared: these investigators diluted the hemolysates with distilled water before making their measurements so that the ionic strengths were probably below the physiologic levels. Cheetham et al,[18] who made their solubility measurements on Hb solutions dialyzed against phosphate buffer, pH 7.0, $\mu = 0.1$, plus 0.2 mol/L NaCl, which together give an ionic strength of $\mu = 0.3$, found no differences in the solubilities of equimolar mixtures of Hb S + A and S + C. Finally, Bunn et al[5] dialyzed the Hb solutions against 0.15 mol/L phosphate for which, at a final pH of about 7.0 to 7.1, $\mu = 0.38$; their addition of 0.055 mol/L sodium dithionite would have raised the value of μ to about 0.54. A possible complicating factor in the experiments of Bunn et al was that all the Hb components used were purified by chromatography on DEAE-Sephadex, which should separate Hb A_2 from Hb A or Hb S, but not from Hb C. Under these conditions and depending on whether the Hb C was obtained from homozygotes (CC) or heterozygotes (SC, AC), the proportion of Hb A_2 in the Hb C samples might be substantially enriched. For example, in the Hb C obtained from an AC hemolysate in which the proportion of Hb (C + A_2) averages about 41%,[19] the percentage of Hb A_2 may thus be increased from the normal 2% to 3% to more than 6%. Since admixture of Hb A_2 inhibits the polymerization of Hb S,[12,18] the solubility of Hb S + C mixtures might be unintentionally raised in relation to the Hb S + A mixtures. It is not possible to predict the precise effect of such enrichment of Hb A_2 on the solubilities since the solubility behavior of mixtures of three Hb components has not been studied. If we take the effect of Hb A_2 addition to Hb S to be similar to that of Hb F and if heterozygote (AC) blood was used to purify Hb C, an enrichment to 6% Hb A_2 would give about 3% Hb A_2 in a final 1:1 Hb S + C mixture. Extrapolation of the data of Sunshine et al[20] indicates that 3% Hb F would result in an increase of about 4.8% in the solubility of the mixture.

The ionic strength range over which the present measurements were made were intended to span the physiologic levels of ionic strength within the red cells as well as the higher levels at which some solubility measurements were made. Without allowing for the contribution of Hb, the main red cell ions, Na^+, K^-, Cl^-, and HCO_3^-, result in an ionic strength of $\mu = 0.12$.[21,22] It is difficult to assess the contribution of organic phosphates such as 2,3-DPG and ATP since they are variably bound to Hb (especially deoxy-Hb), but the total ionic strength, without Hb, should not exceed 0.13 to 0.14. No specific value can readily be assigned to the ionic strength contribution of Hb. Our findings that the solubility differences between mixtures of deoxyhemoglobins S + A and S + C are smaller at starting total Hb concentrations of 34 g/dL than at 26 g/dL, however, are consistent with the possibility that the contribution of Hb to the total ionic strength in the red cell is significant. The mechanism for the additional effect of a 2,3-DPG addition in raising the Hb S + C solubility towards that of Hb S + A is unknown. Although 2,3-DPG alone appears to have no clear effect on the solubility of deoxy-Hb S,[23,24] it could have a specific effect on the solubility behavior of deoxy-Hb C, alone or in the mixture.

Apart from the smaller solubility differences between the S + A and S + C mixtures at higher initial total Hb concentrations (34 g/dL), we also observed a large increase in the observed solubilities of both mixtures under these conditions compared with starting Hb concentrations of 26 g/dL. At least part of this increase can be attributed to enrichment of the sol phase with larger amounts of nonpolymerizing species. Nevertheless, our solubilities for both mixtures are considerably higher than those of Bunn et al[5] whose starting total Hb concentrations were nearly as high as ours. The most obvious difference between their experimental conditions and those of the present experiments is the much higher ionic strength of their solutions ($\mu = 0.54$ v 0.12

to 0.14 in the experiments of Table 1). It is conceivable that with increasing ionic strength beyond 0.4, the limit in our studies, the solubilities of these Hb mixtures fall. Another possible source of difference might be the solution pH: this was 7.0 to 7.1 in the present experiments, but in those of Bunn et al, the addition of 50 mmol/L dithionite would be expected to lower the pH further. At 38 °C, the decrease in deoxy-Hb S solubility with decreasing pH was reported to be quite steep.[25] It was beyond the scope of the present studies, however, to test all these possibilities or to try to reproduce the exact experimental conditions of various investigators.

Previous studies of the interactions of Hb S with other Hb types or mutants indicated that facilitation or inhibition of gelation, in relation to Hb S + A mixtures, was mediated by the formation of asymmetric hybrid tetramers of the type $\alpha_2\beta^s\beta^x$ (or $\alpha_2\beta^s\gamma$, $\alpha_2\beta^s\delta$).[16,26] One or more amino acid residues in the trans–β chain (not containing the β6Val contact site) could then be implicated as a probable intermolecular contact in the deoxy-Hb S polymer. The lower solubility of deoxy-Hb S + C mixtures (compared with deoxy-Hb S + A) appeared paradoxical in this context since considerable evidence both from gelation studies with Hb mixtures[6] and from studies of the deoxy-Hb S crystal double strand[7] seemed to exclude involvement of the NH_2 terminal region of the trans–β chains in polymer contacts. The present results, showing no differences in the solubility of deoxy-Hb S + C mixtures with and without hybrid formation and essentially the same solubilities of the cross-linked hybrids $\alpha_2\beta^s\beta^c$ and $\alpha_2\beta^s\beta^A$, suggest that the lower solubility of the Hb S + C mixtures occurs by a mechanism independent of asymmetric hybrid formation and therefore different from the mechanism underlying the observed behavior of Hb S with several other mutants.[16,26] It was observed earlier in this laboratory[27] that the MGC of both Hb S and Hb A + S mixtures varied with the ionic strength of the medium and was lowest at very low ionic strength. The MGC of deoxy-Hb S varied similarly with ionic strength (not with molarity) in potassium phosphate and in NaCl or KCl. These findings were interpreted to suggest that electrostatic bonds are involved in deoxyhemoglobin S polymerization as well as the hydrophobic interactions suggested by the negative temperature coefficient of gelation. Our findings of a large ionic strength dependence of the solubility of deoxy-Hb S + C mixtures suggest that the difference from Hb S + A mixtures somehow depend on the charge of the substituted residue in Hb C, β6Lys$^+$.

If asymmetric hybrid tetramer formation is not involved in the solubility-lowering effect of Hb C in deoxyhemoglobin S + C mixtures, the question remains as to what is the mechanism of the different behavior of Hb C and Hb A. One possibility is that deoxy-Hb C itself may crystallize to some extent under the conditions of these experiments. Such a possibility was considered by Bunn et al[5] as an explanation for their findings that in Hb S + C mixtures containing more than 60% Hb C the solubilities were slightly lower than those expected from their copolymerization model. The solubilities of deoxy- and CO-Hb C and Hb A have been compared, however, only at ionic strengths of 0.6 or higher[28]; at $\mu = 0.6$ (in phosphate buffer, pH 7.2), deoxy-Hb C was considerably less soluble than the CO-forms. Thus, some deoxy-Hb C might crystallize, lowering the overall solubility of the deoxy-Hb S + C mixtures, but this possibility would require further measurements of the solubilities of Hb C and Hb A at lower ionic strengths.

Another possible mechanism of the lower solubility of deoxy-Hb S + C mixtures that does not involve asymmetric hybrids could be that some tetrameric Hb C might be incorporated into the Hb S polymers. Incorporation of non-S tetramers, both Hb A and Hb C, was suggested earlier by Allison[2] and Bertles et al,[29] the latter based on evidence of incorporation of both deoxyhemoglobins A and C into the solid phase of centrifuged gels of Hb S + A and Hb S + C mixtures. Although some more recent analyses have calculated that non-S Hb tetramers, unlike hybrid tetramers containing a β^s chain, are excluded from the polymer phase,[29,30] the opposite conclusion was reached by other investigators,[17,31] and more direct analyses of the polymer composition will be required to resolve this question.

Since the differences in solubility between deoxyhemoglobins S + C and S + A were quite small when measured at starting total Hb concentrations found in red cells and were reduced further upon addition of physiologic levels of 2,3-DPG, the present results appear to substantiate the major conclusion of Bunn et al[5] that the main causes of the increased sickling tendency and greater clinical severity of sickle cell–Hb C disease over sickle cell trait are the higher proportion of Hb S and higher intracellular Hb concentrations occurring in S + C red cells. The small solubility differences between Hb S + C and Hb S + A expected to occur with red cell Hb and 2,3-DPG concentrations must play a minor role in determining clinical severity.

Separation of the Acetylcholinesterase-Deficient Red Cells in Paroxysmal Nocturnal Hemoglobinuria

By Feng-Lan Chow, Sharon E. Hall, Wendell F. Rosse, and Marilyn J. Telen

Blood of patients with paroxysmal nocturnal hemoglobinuria (PNH) most often contains two or more populations of erythrocytes—one population with normal sensitivity to lysis by complement (PNH I cells) and a second population of moderately abnormal cells (PNH II cells) or markedly abnormal cells (PNH III cells). PNH II and III cells exhibit moderately and markedly increased sensitivity to lysis by complement, respectively, as well as other membrane defects. We have devised a method for isolating pure, intact PNH II and III cells from mixed populations by use of monoclonal antibodies and cell affinity chromatography. Study of purified cell populations has led to the identification of a further subtype, PNH IIIb, of PNH erythrocytes. PNH IIIb erythrocytes are less sensitive to complement lysis than PNH IIIa cells but are lysed by fluid-phase activation of complement, unlike PNH II erythrocytes.
© 1986 by Grune & Stratton, Inc.

PAROXYSMAL nocturnal hemoglobinuria (PNH) is characterized by red blood cells that are abnormally sensitive to the hemolytic action of complement.[1,2] This abnormality is usually present in some but not all red cells; thus, populations of red cells with different sensitivity to the hemolytic action of complement are present in the circulation. Three degrees of sensitivity to complement have been described[3,4]: some of the red cells may be normal (PNH I cells), some may be moderately (two- to fourfold) more sensitive than normal (PNH II cells), and some may be markedly (15- to 25-fold) more sensitive than normal (PNH III cells). These populations occur in various combinations and various proportions in different patients with PNH. It is this mixture of cells that has made it difficult to analyze the membrane defect leading to increased lysis by complement.

In 1960, Auditore et al found that the activity of the enzyme acetylcholinesterase was variably deficient on the red blood cells of patients with PNH.[5] Kunstling and Rosse demonstrated that it was the cells that were abnormally sensitive to the lytic action of complement that were deficient; the normal PNH I cells appeared to have normal amounts of the enzyme.[6] Recently, Chow et al demonstrated by the use of monoclonal antibodies to the enzyme that the protein immunologically characteristic of the enzyme was lacking in these cells.[7] In the present paper, we demonstrate how these facts have been used to devise a technique to separate the complement-sensitive from the complement-insensitive red cells in the blood of patients with PNH. We have used this technique to define a fourth variant population in PNH red blood cells, a subpopulation of PNH III cells that are slightly less sensitive to complement lysis than the majority of PNH III cells.

MATERIALS AND METHODS

Red blood cells. Blood from normal donors or patients with PNH was stored under sterile conditions in Alsever's solution.[8] At the time of use, the erythrocytes were washed in phosphate-buffered saline (PBS), pH 7.4, and adjusted to a concentration of 2×10^8/mL.

Antibodies. Monoclonal antibodies (AE-1, AE-2, AE-3, and AE-4) made by mouse hybridomas against four different epitopes of the acetylcholinesterase molecule were the kind gift of Dr D. Fambrough[9] in the form of purified IgG. In addition, AE-1 and AE-2 hybridoma cells were obtained from American Type Culture Collection and grown as ascites tumors in BALB/c mice. P3 (P3x63/Ag8), the immunoglobulin product of a murine myeloma cell line, was also grown as murine ascites tumors and used as an isotype specific (IgG1) control for the reactions of the AE monoclonal antibodies.

Antibody to mouse IgG made in rabbits was obtained as affinity-purified IgG from Cappel Laboratories, Malvern, Pa. This was shown to react with monoclonal antibody attached to red blood cells by bindng of radiolabeled staphylococcal protein A (SPA).

Complement lysis sensitivity tests. The sensitivity of human red cells to the lytic action of complement was determined by a modification of the complement lysis sensitivity (CLS) test of Rosse and Dacie.[3] The total reaction volume was reduced to 375 μL, but the proportions and materials remained the same. The value used to compare sensitivity of different cell populations to lysis by complement is the CLS H_{50}, defined as the reciprocal of the dilution of serum used (270 in these studies) divided by the milliliter equivalents of serum required to obtain lysis of 50% of the cells.

Binding of monoclonal antibodies to normal red cells. To determine which monoclonal antibodies best bound to the acetylcholinesterase on normal cells, equal volumes (100 μL) of a 5% suspension of washed normal red blood cells and a saturating dilution of monoclonal antibody (or a comparable dilution of control ascitic protein [P3]) were incubated at room temperature for 30 minutes. The cells were then washed twice, brought to a volume of 100 μL, and incubated with an equal volume of rabbit antimouse IgG (2 mg/mL diluted 1:50) at room temperature for 30 minutes. After washing, the cells were again suspended in 100 μL and incubated with 100 μL of ^{125}I-labeled SPA (8×10^4 cpm). Triplicate aliquots of 50 μL each were layered on a mixture of phthalate esters (1.5 parts *N*-butyl phthalate, Fisher Scientific Co, Pittsburgh, Pa to one part bis-2-ethylhexyl phthalate, Eastman Kodak Inc, Rochester, NY) in plastic microcentrifuge tubes and centrifuged in a Beckman microfuge (Beckman Instruments, Fullerton, Calif). The cells were removed by clamping and cutting the tube, and the radioactivity was counted in a well-type scintillation counter.

Separation of red blood cells on a column. Washed red cells (1×10^8/mL) were incubated with equal volumes of each monoclonal antibody (AE-1 and AE-2) at a dilution that saturated all

sites for 30 minutes at room temperature on a rocker platform. They were washed by centrifugation, suspended to the original volume, and incubated with an equal volume of rabbit antimouse IgG (1:50) for 30 minutes at room temperature on a rocker. After two washes, they were pipetted onto the top of the separation column.

The separation column consisted of 10 mL of Sepharose 6MB to which SPA had been covalently attached (obtained from Pharmacia Fine Chemicals, Piscataway, NJ). The column was packed by gravity and washed thoroughly with PBS buffer containing 1% bovine serum albumin before each use.

After application of the cells, the flow rate was adjusted to about 0.2 mL/min; this flow rate was maintained until no further cells could be eluted from the column (usually about 50 minutes). The flow rate was then increased to 3 to 4 mL/min again until no further cells were eluted.

The column was regenerated by thorough (ten-bed volume equivalents) washing with 0.1 mol/L glycine-HCl buffer, pH 3, containing 0.1 mol/L NaCl. It was then thoroughly washed with PBS and stored at 4°C in 0.1 mol/L phosphate buffer with sodium azide (0.05% w/v) pH 6.0.

RESULTS

Binding studies. As shown in Table 1, the monoclonal antibodies AE-1, AE-2, and AE-3 all bound via rabbit antimouse IgG about the same amount of radiolabeled SPA to red cells; AE-4 bound less under similar conditions. Studies using AE-2 monoclonal antibody and radiolabeled $F(ab')_2$ antimouse IgG (Amersham Corp, Arlington Heights, Ill) showed that maximum binding of the radiolabeled anti-IgG was ten to 50 molecules per cell, indicating an extremely low density of antigen. No great increase in binding of radiolabeled SPA was found with combinations of monoclonal antibodies except in the case of the mixture of AE-1 and AE-2. For this reason, this combination was used for the chromatographic separation experiments.

Chromatography of normal red blood cells. When normal red blood cells sensitized with AE-1 and AE-2 and rabbit antimouse were chromatographed on the Sepharose 6MB-SPA column, no cells were eluted during the first (slow flow) phase; 80% ± 5% of the cells were eluted during the rapid flow phase. Cells not sensitized or sensitized with P3 and treated in the same way were eluted during the first (slow) phase (80% ± 10%). This indicated that red blood cells that had the acetylcholinesterase enzyme and that had been reacted with the antiacetylcholinesterase monoclonal antibodies were specifically retained on the column under these conditions.

Table 1. Binding of SPA to Normal Erythrocytes by Monoclonal Antibodies to Acetylcholinesterase and Rabbit Antimouse IgG

Antibody*	^{125}I-Labeled SPA (cpm Bound)
AE-1	5,491
AE-2	5,777
AE-3	5,115
AE-4	1,254
AE-1 + AE-2	7,319
AE-1 + AE-3	6,612
AE-1 + AE-4	6,077
AE-2 + AE-3	6,557
AE-2 + AE-4	6,037
AE-3 + AE-4	6,098
P3 control	389

*All antibodies used in saturating amounts, as determined by binding of radiolabeled antimouse Ig.

To test the ability of the column to separate antibody-coated cells from those not coated by antibody, type A red cells from a normal donor were coated with AE-1 plus AE-2 and rabbit antimouse IgG; type O cells from a normal donor were reacted with the control protein, P3. The cells were

Fig 1. **Separation of the populations of PNH cells by affinity chromatography. After incubation with monoclonal antibodies to acetylcholinesterase and rabbit antimouse antibody, PNH red cells were applied to a column containing Sepharose 6MB to which SPA was covalently attached. The PNH I cells bearing acetylcholinesterase were retarded (upper band), whereas those lacking the enzyme (PNH III cells) passed through the column (lower band).**

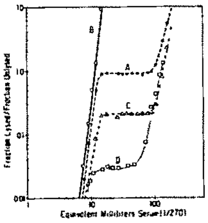

Fig 2. Analysis of the sensitivity to complement lysis of PNH I and PNH III cells separated by affinity chromatography. The analysis of the CLS of the unseparated cells is shown in curve A; 50% of the cells were PNH I, and 50% were PNH III. The analysis of the CLS of the cells eluted from the column by slow flow rate is shown in curve B; these cells were entirely PNH III cells since the CLS curve forms a straight line. Results of the CLS of the cells retained on the column in the first passage are shown in curve C; the proportion of PNH I cells was increased from 50% to 83.3%. When these cells were rechromatographed, the proportion of PNH I cells in the retained cell population increased to 97.1%, as shown by curve D.

mixed and chromatographed through the column. Two separate populations were evident during the slow elution phase, with only type O cells eluted during this phase as shown by lack of agglutination of the eluted cells with anti-A. The type A cells were eluted during the phase of rapid flow.

Chromatography of PNH red blood cells. When PNH red blood cells of the common phenotype (PNH I and PNH III cells) were treated in this way, there was a separation on the column into two distinct populations (Fig 1): one population eluted from the column during the first (slow) phase of the elution process, the other eluted during the rapid elution phase. When these separated cells were tested in the CLS test, those that were not adherent to the column were entirely PNH III cells (Fig 2, line B). Those that were adherent were a mixture of the two populations but were enriched for PNH I cells (Fig 2, curve C). If the cells retained on the column and eluted with rapid flow were again passed through the column, they were further enriched for PNH I cells (Fig 2, curve D), indicating that the contaminating PNH III cells did not remain on the column because of a specific reaction with the column.

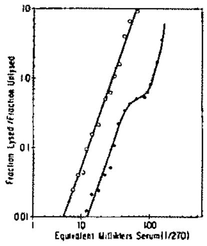

Fig 3. Analysis of the sensitivity to complement lysis of PNH I and PNH II cells separated by affinity chromatography. The analysis of CLS of the unseparated cells is shown in solid symbols; 66% of the cells were PNH 1, and 34% were PNH II. The analysis of CLS of the cells eluted from the column by slow flow rate is shown in open symbols; these cells were entirely PNH II cells. The CLS of the PNH II cells was not changed by passage through the column. Lysis of 50% of the purified PNH II cells occurred at approximately 29-mL equivalents of serum, whereas lysis of 50% of the PNH II cells within the unseparated cell suspension occurred at approximately 35-mL equivalents of serum.

*CLS H_{50} is quantitated by determining the reciprocal of the dilution of serum containing a normal amount of complement, 1 mL of which would lyse 50% of the sensitized cells of a population in a total volume of 7.5 mL. Normal CLS is 2 0 to 3 2 CLS H_{50} units

When cells containing PNH I and PNH II cells were treated as previously described and passed through the column, the PNH II cells were also eluted during the slow elution phase. The cells that were eluted during the slow elution phase were pure PNH II cells (Fig 3).

The use of the column to define a subpopulation of PNH III cells. The red cells of 11 patients who were defined as having PNH I and PNH III cells by conventional CLS testing were separated on the column by the aforementioned procedure. When the red cells lacking acetylcholinesterase were tested in the CLS test, six of 11 were found to be of a single population in that the analysis demonstrated a single straight line (as in curve B, Fig 2). However, in four of 11 patients, there appeared to be a second population of cells that were slightly less sensitive than the PNH III cells as previously defined (Table 2 and Fig 4). The cells of one patient appeared to consist entirely of these slightly less sensitive cells (Table 2). When the PNH III cells from these four patients were isolated by affinity chromatography and lysed by complement activated in the fluid phase by cobra venom factor, 100% of the PNH III cells from each patient were lysed. Thus, the slightly less complement-sensitive

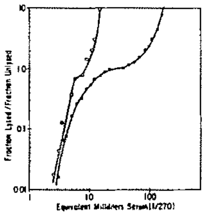

Fig 4. Analysis of the sensitivity to complement lysis of PNH I, PNH IIIa, and PNH IIIb cells separated by affinity chromatography. The analysis of CLS of the unseparated cells is shown in solid symbols; 50% of the cells were PNH I, and 50% were PNH IIIa + PNH IIIb. The analysis of CLS of the cells eluted from the column by slow flow rate is shown in open symbols; 43% of these cells were PNH IIIa cells, and 57% were PNH IIIb cells.

PNH III cells did not resemble PNH II cells in this respect.[10] We have named these intermediate cells PNH IIIb cells and the more complement-sensitive, common variant, present in ten of 11 examples, PNH IIIa cells.

DISCUSSION

One of the facts that has made it difficult to search for the nature of the membrane defect in PNH red cells that renders them susceptible to the lytic action of complement is the existence, in most patients, of a mixture of red cell populations. Thus, the results of biochemical analyses have depended upon the proportion of abnormal cells present, and it has been difficult to define which of the observations were pertinent to abnormal cells. In the past, this difficulty has been minimized by the use of cells of patients with large porportions of abnormal cells.[11-13] However, such patients are rare, and their rarity makes statistical analysis of findings derived from them difficult in that comparisons among patients cannot be readily made.

Previously, PNH I and PNH II cells have been separated from PNH III cells by differential lysis.[14] PNH III, but not PNH I or PNH II, red cells bind the membrane attack complex when it is initiated in fluid phase by cobra venom factor and are lysed by this process.[10] The PNH III cells in a mixture of cells are lysed by cobra venom factor and serum, and the surviving non–PNH III cells can thus be purified. However, the surviving population(s) (usually PNH I cells) is often the one that is not under investigation. Further, the membranes of the populations that are lysed by complement are contaminated by the presence of complement components; this may interfere with the analysis of their structure.

Suspensions of intact cells enriched by complement-sensitive cells can be obtained by differential centrifugation since the proportion of abnormal cells tends to be greater in the young and hence less dense cells.[3] This is because the proportion of abnormal (PNH III) cells that are delivered to the circulation is much greater than the proportion of these cells in the peripheral blood.[15] However, the enrichment for PNH III cells by centrifugation is always incomplete, and the abnormal cells are contaminated by the normal PNH I cells.

The technique described in this paper allows for the first time the separation of the abnormal cells in PNH from the normal PNH I cells by taking advantage of the fact that these abnormal cells lack the protein for the enzyme acetylcholinesterase.[7] Since the antibodies that are used in these studies do not react with the abnormal cells, there is little or no contamination of the membrane with immunoproteins and no disruption of membrane structure. The cells are isolated whole, and the characteristics of lysis in response to complement activation can be analyzed. Further, the presence of the monoclonal antibodies to acetylcholinesterase and antimouse IgG has no effect on the sensitivity of the PNH I and normal red blood cells to complement lysis. This is probably because the number of copies of the antigen is so small compared to the number of copies of the antigen against which the anti-I antibody reacts in this test (probably greater than 600,000 per cell).[16] It is also the low density of acetylcholinesterase molecules[7] that allows normal and PNH I cells to be eluted from the column by increased flow rate alone, without changes in pH or the addition of denaturing agents.

The advantages of such separations in the analysis of the abnormalities of the red cells in PNH are illustrated in the ability to define a new subpopulation of PNH III cells. These cells are so little different from the usual PNH III cells that they were not detected in the analysis of complement sensitivity of mixed populations of red cells. Only when the abnormal cells were separated did the difference become apparent. Nevertheless, the identification of these cells has clarified the interpretation of the CLS curves of some patients.

We have also used this technique to separate the abnormal cells for analysis of the presence of decay-accelerating factor (DAF), a membrane protein that normally controls the formation and activity of the C3 convertases of complement.[17] This protein is completely or partially lacking in the complement-sensitive red cells of PNH.[18,19] By the use of separated populations, we have been able to demonstrate the effects of the absence of DAF and of the repletion of DAF purified from normal cells.[20] The nature of the relationship between acetylcholinesterase deficiency and DAF deficiency is currently under investigation.

By the use of the techniques described herein, purified populations of PNH cells can be obtained from nearly all patients with PNH. This will markedly simplify the analysis of these cells for the nature of their membrane defect(s) and will allow more ready comparison of the cells of different patients.

ACKNOWLEDGMENT

We wish to acknowledge the technical assistance of Mary Bass. We wish to thank Dr Douglas Fambrough for providing the antibodies used in these studies.

Analysis of Leukocyte Differentiation Antigens in Blood and Bone Marrow From Preleukemia (Refractory Anemia) Patients Using Monoclonal Antibodies

By Peter Hokland, Gitte Kerndrup, James D. Griffin, and Jørgen Ellegaard

Peripheral blood and bone marrow mononuclear cells from patients with refractory anemia (RA) or RA with sideroblasts (defined according to the revised French-American-British classification with less than 5% blast cells in the bone marrow) were analyzed using a panel of monoclonal antibodies directed against leukocyte antigens on B lymphocytes, T lymphocytes, monocytes, and myeloid cells. In the peripheral blood an increased proportion of T lymphocytes (and correspondingly a decreased proportion of B cells) could be demonstrated. However, when expressed in terms of absolute numbers, the T cell component was depressed because of severely decreased numbers of T4+ helper cells. In contrast, the absolute numbers of T8+ suppressor cells were either normal or increased in the majority of the patients. This resulted in markedly decreased ratios of T4+/T8+ cells, which were closely correlated to the number of transfusions given to the patients because of their refractory anemia. Finally, nearly all of the patients exhibited decreased numbers of cells reactive with the N901 natural killer (NK) antibody, thus explaining our earlier finding of decreased NK activity in these patients. In the bone marrow increased proportions of myeloid cells reactive with monoclonal antibodies present on immature myeloid cells (My7 and My9) were found, suggesting the presence of malignant clones. Indeed, when the numbers of My7+ cells and the morphologic evaluations of bone marrow smears at the time of diagnosis were compared to the progression of the disease, a group of patients with high numbers of My7+ cells and normal morphology could be identified that had a high probability of progression to refractory anemia with an excess of blasts or to overt acute myeloid leukemia. Thus, the use of antibodies defining leukocyte differentiation antigens might be of significant value in the diagnosis and prognostication of the myelodysplastic syndromes. These findings are discussed in relation to the pathogenesis of this potentially premalignant condition with special emphasis on possible defects in the immunologic defense mechanisms against early neoplasias.

© 1986 by Grune & Stratton, Inc.

ACUTE MYELOID LEUKEMIA (AML) is in some patients preceeded by a myelodysplastic phase in which varying degrees of bone marrow dyshematopoiesis are dominant features. The term myelodysplastic syndrome includes five subgroups distinguished by their different percentages of blast cells in the bone marrow and peripheral blood according to the recent revision of the French-American-British classification of acute myeloid leukemias.[1] There, refractory anemia (RA) is defined as a condition with fewer than 5% myeloblasts in the bone marrow, and this strengthening of the diagnostic criteria has had the advantage of defining a more homogeneous group of patients in which potentially premalignant processes can be studied.

Even though much is known about the growth characteristics[2] and cytogenetics of bone marrow cells,[3] information about the immune system in these patients is still scarce. Since several parameters of the immune system have been envisaged to play a role in the defense against early neoplasias, this condition seems to be well suited for elucidating immunologic alterations in potentially premalignant conditions We have previously demonstrated that patients fulfilling the new and more strict criteria for preleukemia exhibit a markedly diminished natural killer (NK) cell activity in peripheral blood, probably because of a low number of circulating NK cells.[4] Here we describe the results from measurements of leukocyte differentiation antigens on blood and bone marrow mononuclear cell suspensions from such patients using a panel of monoclonal antibodies (MoAb) suited for evaluating both lymphocyte subsets as well as myeloid cells. Although these patients were found to be heterogeneous with respect to antigen expression, we were able to detect several abnormalities of potential interest in relation to the prognosis of this group of patients.

MATERIALS AND METHODS

Patients. Thirty-two patients, 17 females and 15 males, were found to fulfill the diagnostic criteria of RA discussed in detail elsewhere[5]; ten patients presented with ring sideroblasts (RA-S). Fifty-five percent had clonal karyotypic abnormalities when examined by chromosome-banding techniques.[6] It should be stressed that all had less than 5% blast cells in the bone marrow and none had myeloblasts in the peripheral blood at the time of diagnosis.

Preparations of mononuclear cell suspension from peripheral blood and bone marrow Freshly drawn, heparinized venous blood was layered onto Isopaque-Ficoll (Nygaard, Oslo), and red cells and mature myeloid cells were removed by density centrifugation.[7] The interface cells were washed twice in Hanks' buffered salt solution (HBSS) supplemented with 2.5% pooled human AB serum and adjusted to a concentration of 1 × 10^6/mL. Bone marrow was suspended in preservative-free heparin and diluted approximately 1:4 in HBSS After Isopaque-Ficoll centrifugation the cells were treated as previously described for peripheral blood cells.

Monoclonal antibodies. The MoAb used in this study are shown in Table 1 together with a summary of their reactivities and original references They were selected to give as complete a picture of the differentiation antigens on T cells, B cells, monocytes, and myeloid cells as possible. B1 (provided by Dr L.M. Nadler) is expressed on B cells and some malignant B cells including 50% of acute lymphoblastic leukemia and 40% of lymphoid blast crisis cells of chronic myeloid leukemia. For the definition of the T3 pan/T cell antigen, the UCHT-1 antibody produced by Dr P.C. Beverley was used. The T4 helper/inducer antigen and the T8 cytotoxic/suppressor antigen were defined by the B.66.6 and the B.99 1 antibodies produced by Dr

B. Perussia. The NK component was evaluated with the N901 antibody. For the evaluation of the myeloid component we used MoAbs of the My-series produced and characterized by J.D. Griffin. The My4 antigen is expressed on mature and immature monocytes as well as on acute monocytic leukemia cells; My7 is expressed preferentially on immature myeloid cells not including the CFU-C. My8 is expressed on more mature myeloid cells and to a certain degree on peripheral blood monocytes. The My9 antigen is expressed on immature myeloid cells including some CFU-C and BFU-E. In contrast, the NAT-9 antibody, which exclusively reacts with mature myeloid cells, was provided by Dr R.B. Andreasen. Finally, HLA-DR antigens were detected using the AAS-1 antibody produced in our laboratory, which reacts with a HLA-DR framework antigen. All antibodies were used as ascites in dilutions varying from 1:50 to 1:450

Indirect immunofluorescence assay Blood and bone marrow cells were adjusted to a concentration of 1 × 10^6/mL, and 0.5 to 1 × 10^6 cells were incubated for 30 minutes at 4 °C with appropriately diluted ascites containing the aforementioned antibodies. After two washes in HBSS plus 2.5% AB serum, the cells were incubated with a rabbit antimouse antiserum (Dakopatts, Copenhagen) at a dilution of 1:20 at 20 °C for 30 minutes. After two additional washes in HBSS plus 2.5% AB serum supplemented with 1% formaldehyde, the number of positive cells reactive with the different antibodies was scored by fluorescence microscopy after counting at least 200 cells.

RESULTS

Analysis of peripheral blood mononuclear cells. Many of the patients exhibited varying degrees of lymphopenia, resulting in decreased absolute numbers of most of the subsets measured. The group of patients was very heterogeneous with respect to B1 antigen expression since only nine of the patients were within normal range, eight patients exhibiting significantly higher numbers and 12 patients exhibiting lower numbers of B lymphocytes. In 23 of 29 patients the absolute numbers of B1+ cells were decreased. Using the anti-My4 antibody–defining monocytes, the same pattern as that seen for B1 was observed. However, very high numbers were seen in two patients who later progressed to chronic myelomonocytic leukemia (CMML) (data not shown).

In Fig 1 the results from the analysis of T cells and their subsets are given. Using the UCHT-1 antibody as a pan-T cell marker, the absolute numbers of cells were decreased in 24 out of 29 patients. With regard to T cell subsets, a marked heterogeneity was observed with respect to the expression of the T4 antigen, which is a reliable marker for the helper/inducer subset. However, strikingly decreased amounts of circulating T4 cells were seen in 27 out of 29 patients. In contrast, 14 of 29 patients showed increased numbers of cytotoxic/suppressor cells as evaluated by MoAb B.99.1 directed against the T8 antigen (Fig 1), with only seven exhibiting slightly decreased circulating T8 cells. These changes are reflected in the ratios between helper and suppressor cells (T4/T8 ratios), which were decreased in 17 of the 29 patients (data not shown). Moreover, four of the patients with normal or increased ratios subsequently converted during the observation period.

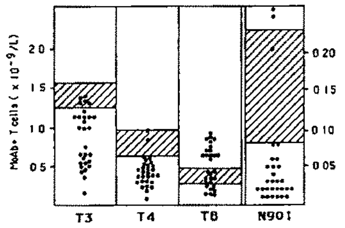

Fig 1. Reactivity of peripheral blood mononuclear cells from 29 patients using T cell-specific reagents: T3, reactivity with UCTH-1 pan-T MoAb; T4, reactivity with the B.66.6 MoAb specific for helper/inducer T lymphocytes; T8, reactivity with MoAb B.99.1 specific for cytotoxic/suppressor T cells; and N901, reactivity with the NK-specific MoAb N901. Hatched areas represent the mean and SD of 15 normal donors. All results are given as absolute numbers (× 10^{-9}/L)

Many reasons for this disturbance in T cell subsets can be envisaged, but in Fig 2 we have related the number of transfusions given to the individual patients to their T4/T8 ratio. It will be seen that with an increasing number of transfusions a steep fall in the T4/T8 ratio is seen during the first 20 transfusions, followed by a more gradual one up to 200 transfusions. Finally, with respect to the analysis of peripheral blood, we looked at the percentage of N901-bearing cells, which have been shown to contain the NK cell fraction.[12] A marked decrease was observed in 26 out of 29 patients (Fig 1), with extremely low numbers (less than 10% of that seen in normal donors) in 14 patients.

Since the aforementioned observed changes in the proportion of lymphocyte subsets could be of major importance in the etiology and pathogenesis of the anemia seen in these patients, we found it of major importance to evaluate the consistency of the observed abnormalities with respect to

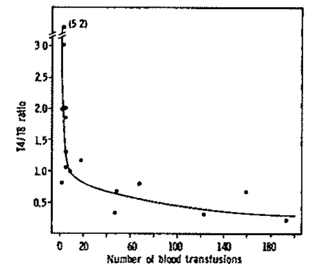

Fig 2. Correlation between T4/T8 ratios and number of blood transfusions given to 16 RA patients in whom inverted ratios had developed as of April 1985.

short-term reproducibility. From Table 2, which shows longitudinal measurements on peripheral blood cells from the same patient on three different occasions, it will be seen that apart from minor fluctuations, the aforementioned observed tendencies were very stable.

Analysis of mononuclear bone marrow cells. Bone marrow aspirations or Jamshidi bone marrow biopsies from the iliac crest were attempted in all patients, and suitable material was obtained in 30 out of 32 patients. In one patient, three different aspirations were performed, all of them contaminated with peripheral blood cells to such an extent that proper analysis could not be performed. In another patient, ordinary aspirations from the sternum resulted in a dry tap, and attempts to recover cells from several Jamshidi biopsies failed. The analysis of the remaining 30 patients is summarized in Figs 3 to 5; not shown are data demonstrating that the mononuclear bone marrow suspensions contained low numbers of both T and B cells as evaluated by B1 and T3 (thus excluding a gross admixture of peripheral blood in these aspirates). Cells of the myeloid lineage were evaluated using five different MoAbs, all related to different stages of myeloid differentiation. In normal humans My7 is usually expressed on less than 10% of mononuclear bone marrow cells, but it will be seen from Fig 3 that the My7 was expressed on an increased percentage of cells in 26 out of 29 patients. In contrast, the expression of My9, which is somewhat more broadly reactive, was increased in only 11 out of 29 patients. The My8 and NAT-9 antibodies react with major fractions of normal bone marrow cells, and from the data shown in Fig 4 it will be seen that between 20% and 70% of the cells from the preleukemia patients expressed these antigens, and only in a minority of cases in increased numbers. Finally, the percentages of HLA-DR–bearing cells in the bone marrows are also shown in Fig 4, and it is clear that few significant increases were observed.

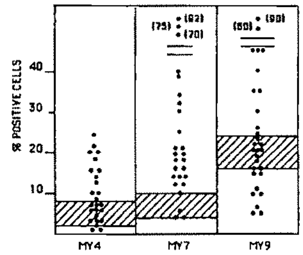

Fig 3. Distribution of monocytoid (anti-My4+) and early myeloid (anti-My7+ and anti-My9) cells in bone marrows from 30 RA patients. Hatched areas represent the mean and SD of six normal donors.

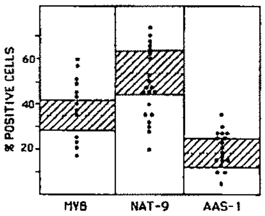

Fig 4. Reactivity of two mature myeloid differentiation antigens (My8 and NAT-9) and HLA-DR (as evaluated by MoAb AAS-1) in RA patients. The mean and SD of six normal donors are shown in the hatched areas.

To further elucidate the significance of the increased percentages of My7+ cells in the bone marrow (Fig 3), we compared them to the morphology and clinical course. Choosing the combined percentages of myeloblasts and promyelocytes as indicators of bone marrow maturity, it could be demonstrated (Fig 5) that patients with subsequent progression from RA or RA-S to RA with an excess of blasts (RAEB) exhibited high numbers of My7+ cells but usually no or modest abnormalities in morphology ($P < .01$, Wilcoxon's rank sum test). Moreover, patients with very high numbers of My7+ cells were characterized by large transfusion needs and fast disease progression either to RAEB, AML, CMML, or death resulting from severe thrombocytopenia related to bone marrow depression.

As was the case with blood specimens, short-term longitudinal studies were also performed on bone marrow cells. From Table 2 it will be seen that in a patient with slightly increased numbers of My7+ cells but stable transfusion needs the antigen expression remained stable for a 12-month period.

DISCUSSION

Until recently, the diagnostic criteria for myelodysplastic syndromes were ill defined, and consequently several groups of patients, including those with CMML, smouldering AML, or RAEB were grouped together in preleukemia patient studies. With the recent definition of diagnostic criteria,[1] a group of preleukemia patients with RA or RA-S are defined as those having less than 5% blasts in the bone marrow and

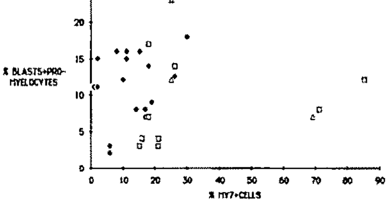

Fig 5. Correlation between My7 reactivity and morphology (combined percentages of myeloblasts and promyelocytes) in RA patient bone marrows at presentation. Key: ◊, patients remaining in RA; □, patients progressing to RAEB; Δ, patients progressing to AML (clinical staging as of April 1985).

less than 1% in peripheral blood, and in this study these diagnostic prerequisites were followed. Consequently, several patients with more than 5% blasts have been excluded from this investigation, but will be described separately.

Until now, laboratory studies in preleukemia patients have mainly consisted of cytogenetic analysis and determination of growth in semisolid agar.[2,3] These studies have shown that the majority of the patients have distinct clonal abnormalities accompanied by altered growth capacities in CFU-C assays, indicating that in at least some of the patients malignant clones are present. In contrast, few studies have dealt with detailed immunologic investigations in these patients in spite of the fact that overt AML develops in some of the patients at a later stage. This condition could thus provide a rare opportunity for studying the immune system at a potentially premalignant stage, and we therefore decided to undertake a detailed study of various aspects of the immunologic response in these patients. Here we have described the results from the analysis of blood and bone marrow mononuclear cells using a panel of MoAb suited for evaluating the major lineages of hematopoiesis.

Even though most malignant blood diseases originate in the bone marrow, evaluation of leukocyte subsets in the peripheral blood can yield valuable information concerning their possible progression and give indications on functional assays that could elucidate their pathogenesis. The most interesting finding emerged from the blood suppressor cells (Fig 1) that resulted from decreased numbers of T4 cells and increased numbers of T8 cells. Similar findings were recently published by Anderson et al in a smaller group of patients,[16] but we have extended these findings considerably by demonstrating that such patients exhibited a marked heterogeneity, with a range of T4/T8 ratio from 0.3 to 5.2. Since suppressor cells are thought to influence erythropoiesis, this heterogeneity might be of importance in determining the cause of the anemic stage in these patients, but we have at present no data suggesting that in patients presenting with low T4/T8 ratios more severe anemia develops than in those with normal ratios. Based on these findings, studies are, however, under way to analyze the influence of T4 and T8 cells (using either fluorescence-activated sorted cells or in vitro propagated T cell clones) on autologous CFU-C and CFU-E.

The anemic stage does in some patients require frequent blood transfusions, and we have—in light of the recent findings of altered T4/T8 ratios in hemophilic patients given factor VIII concentrate[17]—tried to correlate the number of transfusions given to the patients and their T4/T8 ratios. As shown in Fig 2, it appeared that patients with the highest number of blood transfusions were the ones with the lowest T4/T8 ratios. We can at present give no explanation for this, but it is tempting to suggest that immunosuppressive agents (microbiologic or nonmicrobiologic) are transferred during blood transfusions. Whether this (or these) agent is related to the ones purportedly demonstrated in patients with acquired immunodeficiencies[18] remains to be established. Another possibility could be that these changes are caused by the transfer of cytomegalovirus (CMV) with the tranfusions, but since these were not screened for CMV, we have not been able to address this question.

To a certain degree, our findings contrast to those of Anderson et al who found a mean T4/T8 ratio of 1.8.[16] However, as previously mentioned, many of these patients do not fit into the more strict criteria for primary preleukemia,[1] and these studies are therefore not readily comparable with ours.

When evaluating the T cell component using pan-T MoAb (Fig 1), an increased percentage of T cells was demonstrated in some of the patients, who also exhibited lowered percentages of B cells, as evaluated by the MoAb anti-B1. These data could suggest that the increased numbers of T8+ lymphocytes exert suppression on the B lymphocyte lineage, but final proof of this awaits functional studies of the in vitro immunoglobulin secretion in these patients, and such are now in progress. It is, however, interesting to note that Anderson et al[16] using anti-immunoglobulin antisera in three preleukemic patients did not find a similar decrease in the number of B cells. These authors did, however, observe a lack of Epstein-Barr virus receptors on B lymphocytes in their patients, and based on this finding it was hypothesized that the B cells in the preleukemia patients might have a deficiency in mature immunocompetent B cells.

The natural history of the development in the single patient from a protracted stage of RA through RAEB to AML is only partly elucidated, and obviously disease parameters of predictive value regarding malignant transformation are highly sought after since these patients are difficult to treat once they have reached the AML stage. With this in mind, the finding of greatest potential interest that emerged from our study is the increased numbers of immature myeloid cells in the bone marrows that reacted with the antibodies anti-My7 and to a lesser extent anti-My9 since this adds considerably to our knowledge of the use of antimyeloid MoAbs in myeloid differentiation disorders. This finding is best seen in light of our comparative studies (Fig 5) that clearly demonstrated that progression from the initial RA stage to RAEB could not be predicted by bone marrow morphology. In contrast, patients with high numbers of My7+ cells (irrespective of morphology) seemed to be the ones susceptible to RAEB progression. In connection with this, it should be noted that progression to RAEB was always accompanied by an increase in My7+ cells in the bone marrow. However, the My7 determinations shown in Fig 5 are all from the time of diagnosis.

The immunologic heterogeneity observed in our patients might be useful in the longitudinal studies performed for the purpose of prognostication and demonstration of changes indicating a transformation to an overt AML. Regarding this, it is noteworthy that during a short observation period (less than 6 months) the antigen expression remained stable, thus demonstrating the validity of these assays (Table 2). The apparent asynchrony between My7 expression and morphology thus indicates that immunologic phenotyping in RA patients should be included in the diagnostic armature. Naturally, My7 is of primary importance in this context, but it might well be envisaged that an immaturity index of a given bone marrow might be constructed that could yield even more information. This might—apart from My7—include HLA-DR antigens that are known to be present on large proportions of AML cells as well as a mature myeloid antigen, eg, NAT9, that, in contrast to My8, is not expressed by monocytes. Consequently, the combined presence of My7 and HLA-DR (AAS-1) and a decrease in NAT-9 expression might be more predictive than My7 alone. Construction of such ratios might possibly also be of importance in monitoring the response to treatment of AML patients.

Our understanding of the immune response against early neoplasias has been drastically altered during the recent years. Earlier assumptions that educated cytotoxic T lymphocytes might kill emerging malignant clones have not been fulfilled, and it is now believed that the NK cell is a more likely candidate for cell-mediated lysis of malignant cells. We have shown earlier that preleukemic patients are deficient in NK function,[4] and here we extend this conclusion by demonstrating decreased numbers of cells reactive with the recently described NK-specific monoclonal antibody N901. This finding strongly indicates that the reason for the deficient NK activity in these patients is a lack of circulating NK cells. Whether this is due to altered migratory capacities of NK cells in these patients (possibly involving selective localization close to abnormal clones of premalignant myeloid cells) is not clear, but estimation of NK activity and N901+ cells from other tissues is under way to resolve the issue. Preliminary results from such experiments do in fact suggest that inhibition of CFU-GM growth can only be obtained after preincubation with peripheral blood mononuclear cells with high NK activity (as measured in a chromium release assay).

In addition to NK cells, T8-positive T lymphocytes might be envisaged to inhibit myeloid growth through the secretion of suppressive factors. The finding of increased proportions of T8-positive suppressor cells in the blood of all patients might support this, but the final answer for this question awaits either semisolid agar experiments or immunoperoxidase staining of bone marrow sections with relevant MoAbs.

In conclusion, we have demonstrated a number of abnormalities in the distribution of leukocyte subsets from blood and bone marrow in primary preleukemic patients. Of these, the decreased T4/T8 ratio in the blood and the increased proportion of cells in the bone marrow possessing the immature myeloid antigen My7 might be of importance in the pathogenesis and for the diagnosis of this potentially premalignant disease.

ACKNOWLEDGMENT

We thank Drs L.M Nadler (Harvard Medical School), B. Perussia (Wistar Institute, Philadelphia), P.C. Beverley (University College Hospital, London), and R.B. Andreasen (Royal State Hospital, Copenhagen) for their kind donation of the MoAbs used in this study.

Deficient Induction of Leukotriene Synthesis in Human Neutrophils by Lipoxygenase-Deficient Platelets

By Kenji Kanaji, Minoru Okuma, and Haruto Uchino

The effect of human platelets with deficient lipoxygenase activities on leukotriene B_4 (LTB_4) synthesis by neutrophils was studied. When arachidonic acid (AA) metabolites obtained from the incubation of washed normal neutrophils and platelets with *N*-formylmethionylleucylphenylalanine (FMLP), cytochalasin B, and AA were analyzed by reversed-phase high-perfomance liquid chromatography, the synthesis of 5-lipoxygenase products, including LTB_4, was remarkably stimulated by platelets, with their maximal effect at a ratio of platelets to neutrophils of 15:1. However, the use of lipoxygenase-deficient platelets obtained from four patients with myeloproliferative disorders instead of normal platelets showed the deficient production of 5-lipoxygenase–derived products, whereas platelets with normal lipoxygenase activities obtained from MPD patients stimulated the 5-lipoxygenase pathway similarly to the way in which normal platelets did. The addition of 12-hydroperoxyeicosatetraenoic acid (12-HPETE), a labile AA metabolite via the platelet lipoxygenase pathway, could activate the 5-lipoxygenase pathway in neutrophils incubated with FMLP, cytochalasin B and AA, but its stable end product, 12-hydroxyeicosatetraenoic acid, could not. Thus, it is suggested that lipoxygenase-deficient platelets did not sufficiently stimulate LTB_4 synthesis during platelet-neutrophil interactions because of defective formation of 12-HPETE. This altered interaction between platelets and neutrophils through the lipoxygenase pathway might result in deficient responses at sites of thrombosis or inflammation in patients with deficient platelet lipoxygenase activities.

© *1986 by Grune & Stratton, Inc.*

ARACHIDONIC ACID (AA) is converted via the 5-lipoxygenase pathway to eicosanoids, including leukotriene B_4 (LTB_4) and 5-hydroxyeicosatetraenoic acid (5-HETE), in polymorphonuclear neutrophils. LTB_4 has potent chemotactic and chemokinetic activities and may be one of the major mediators of neutrophil function.[1] On the other hand, platelets contain 12-lipoxygenase as well as cyclooxygenase. The former enzyme converts AA to 12-hydroperoxyeicosatetraenoic acid (12-HPETE), which is reduced by peroxidase to 12-hydroxyeicosatetraenoic acid (12-HETE).[2] Although the significance of the platelet 12-lipoxygenase pathway in platelet function is still obscure, recent studies have demonstrated the presence of biochemical interactions between platelets and neutrophils via lipoxygenase enzymes. Borgeat et al have shown that 5S,12S-dihydroxyeicosatetraenoic acid (5S,12S-diHETE) is a product of the successive reactions of AA with 5-lipoxygenase and 12-lipoxygenase.[3,4] Marcus et al have demonstrated that AA and 12-HETE derived from platelets serve as substrates for eicosanoid formation by neutrophils[5] and that both neutrophils and platelets need to be activated by a strong stimulus such as calcium ionophore A23187 for the production of significant amounts of 5S,12S-diHETE.[5,6] Furthermore, Maclouf et al have reported that platelet-derived 12-HPETE stimulates LTB_4 synthesis in human blood leukocytes,[7] a finding that remains to be confirmed by other laboratories.[8]

Patients with myeloproliferative disorders (MPD) are known to have a high incidence of infections,[9] probably because of abnormal leukocyte function. Since LTB_4 may regulate neutrophil function,[10] it might be assumed that LTB_4 synthesis is decreased in these patients. The deficient production of LTB_4 may result not only from abnormalities of neutrophils themselves[11] but also from abnormalities of platelets because platelets in some MPD patients are known to be deficient in 12-lipoxygenase activity.[12,13]

In this study, we investigated the effects of platelets on AA metabolism by neutrophils, especially concerning LTB_4 synthesis, when stimulated with *N*-formylmethionylleucylphenylalanine (FMLP) and AA in the presence of cytochalasin B. Lipoxygenase-deficient platelets from MPD patients show a decreased activation of LTB_4 synthesis in neutrophils, possibly because of deficient production of 12-HPETE by the platelets.

MATERIALS AND METHODS

Patients and normal controls. Eight patients with MPD were investigated: three with chronic myeloid leukemia (CML) in the stable phase, two with polycythemia vera (PV), and three with essential thrombocythemia (ET) Diagnosis was determined by standard methods as described previously.[12] Platelet AA metabolism was estimated by the thiobarbituric acid method[14] by which deficient activities of the platelet lipoxygenase pathway were demonstrated in four of the eight patients. Seven normal volunteers were also studied as controls. Informed consent was obtained from all subjects.

Preparation of cell suspensions. Blood from normal donors and patients who had taken no drugs known to affect AA metabolism for at least 2 weeks before venipuncture was collected in 3.8% trisodium citrate solution (9 vol blood to 1 vol citrate) and centrifuged for the preparation of platelet-rich plasma as described previously.[15] Neutrophils were prepared as described previously[11] and suspended in the incubation buffer (pH 7.4) containing 50 mmol/L Tris-HCl, 101 mmol/L NaCl, and 5 mmol/L glucose. Neutrophil preparations from normal donors always contained more than 95% segmented neutrophils, and percentages of contaminating platelets were less than 30. Platelets were washed as described previously[12] and finally suspended in the incubation buffer. Contamination of the platelet suspension by erythrocytes and leukocytes was negligible.

Preparation of 12-HPETE and 12-HETE. 12-HPETE and 12-HETE were prepared by a modification of the procedure reported by Pace-Asciak et al.[16] In short, washed human platelets

were resuspended in 50 mmol/L Tris-buffered saline, pH 7.4 (0.8 × 10^9 platelets/mL), and disrupted sonically.[17] After the lysate (8 mL) was incubated with 200 μmol/L AA in the presence of 100 μmol/L indomethacin for five minutes at 37 °C, the incubation mixture was placed on ice, immediately followed by the addition of ice-cold methanol (8 mL) and ice-cold diethyl ether (24 mL), and the mixture was acidified to pH 3.0 with 0.2 mol/L HCl. The ether phase was separated by rapid centrifugation at 4 °C and washed with 3 mL of ice-cold water. The ether phase was finally dried over anhydrous sodium sulfate and evaporated to dryness under nitrogen. The residue was dissolved in hexane and purified by high-performance liquid chromatography (HPLC) using a column of Nucleosil 50-5 (4.6 × 250 mm, Macherey-Nagel, Düren, Germany) and a mobile phase consisting of hexane/isopropanol/acetic acid (98.2:0.1, vol/vol) at a flow rate of 1 mL/min. An Altex model 110A single-pump chromatograph (Altex Scientific, Berkeley, Calif) with a Soma S-310A variable-wavelength spectrophotometer detector (Soma Optics, Tokyo) was used The identity of 12-HETE was confirmed by gas chromatography–mass spectrometry,[11] and that of 12-HPETE was confirmed by reductive conversion to 12-HETE with stannous chloride.[12] Quantitation was done by using UV absorption at 237 nm in ethanol.[18] The purified material was dissolved in acetone, stored under nitrogen at −70 °C, and used within 2 weeks The products used in the experiments were more than 97% pure, based on the HPLC analysis.

Incubation and extraction Unless otherwise specified, after cell suspensions containing 3 × 10^7 neutrophils and 0 to 75 × 10^7 (routinely 45 × 10^7) platelets/mL were incubated with cytochalasin B (5 μg/mL) for five minutes at 37 °C, the mixtures were incubated with 10 μmol/L FMLP and 60 μmol/L AA for another five minutes at the same temperature In experiments with 12-HPETE and 12-HETE, each was transferred to an assay tube, and the solvent was evaporated under nitrogen Neutrophil suspensions (3 × 10^7 cells/mL) preincubated with cytochalasin B (5 μg/mL) for five minutes at 37 °C were transferred to the assay tube without delay, immediately followed by the addition of 10 μmol/L FMLP and 60 μmol/L AA, and then the mixtures were incubated for another five minutes at the same temperature. When the calcium ionophore was used, neutrophils (3 × 10^7 cells/mL) were incubated with 10 μmol/L A23187 and 60 μmol/L AA for five minutes at 37 °C. In all experiments with cell suspensions, 1 mmol/L $CaCl_2$ was added just before the incubation at 37 °C. The incubation was terminated by the addition of 4 vol ethyl acetate after acidification by 0.2 mol/L HCl to pH 3.0, and 450 ng of prostaglandin B_2 (PGB_2) was added as an internal standard. Extraction and evaporation were performed as described previously[11] and evaporated residue dissolved in 30 μL methanol was subjected to chromatography as follows.

FMLP dissolved in the incubation buffer (1 mmol/L) and cytochalasin B in dimethyl sulfoxide (2 mg/mL) were stored at −20 °C and diluted with the incubation buffer when used. AA and A23187 were dissolved as described previously.[14,19] Dimethyl sulfoxide was at a final concentration of less than 0.25%.

HPLC analysis. Reversed-phase HPLC was routinely carried out using a column of Nucleosil $_7C_{18}$ (4.6 × 250 mm, Macherey-Nagel). The chromatograph and detector were the same as those used for preparation of 12-HPETE. A 10-μL aliquot of each sample was analyzed by the use of a mobile phase I consisting of methanol/water/acetic acid (75:25:0.01, vol/vol) at a flow rate of 1 mL/min.[20] Another 10-μL aliquot was analyzed by a mobile phase II consisting of tetrahydrofuran/methanol/water/acetic acid (25:30 45:0.1, vol/vol) at a flow rate of 0.9 mL/min for the resolution of LTB_4 and 5S,12S-diHETE.[21] Column effluent was monitored at 270 nm for PGB_2, LTB_4, and 5S,12S-diHETE and at 235 nm for 12-hydroxyheptadecatrienoic acid (HHT), 12-HETE, and 5-HETE. The amounts of 5-lipoxygenase–derived products were quantitated by comparing their peak areas with that of the internal standard (PGB_2). Th extinction coefficients used were determined in each mobile phase using a Hitachi Model 200-20 spectrophotometer (Hitachi, Tokyo) 48,700 for LTB_4 in the mobile phase (II), 27,900 for 5-HETE in the mobile phase (I), and 23,100 and 22,400 for PGB_2 in the mobile phase (I) and (II), respectively. The extinction coefficient of 5S,12S-diHETE was assumed to be identical with that of LTB_4. Identification of LTB_4, 5-HETE and 12-HETE was performed by gas chromatography–mass spectrometry.[11] 5S,12S-diHETE and HHT were identified by comparisons of the chromatographic behaviors of each authentic sample.

Materials. FMLP and cytochalasin B were obtained from Sigma Chemical Co, St Louis; authentic 5S,12S-diHETE was kindly donated by Dr Shozo Yamamoto, Department of Biochemistry, Tokushima University School of Medicine, Tokushima, Japan Authentic HHT was prepared biosynthetically as previously described.[12] The other agents were the same as described previously.[11]

RESULTS

The incubation of neutrophils with FMLP, cytochalasin B, and AA led to the formation of small amounts of 5-lipoxygenase products, including LTB_4, 5S,12S-diHETE, and 5-HETE, as illustrated in Fig 1A and 1C. However, the production of 5-lipoxygenase metabolites, especially LTB_4, was remarkably activated in the presence of platelets as shown in Figs 1B and 1D. Platelets (45 × 10^7 cells/mL) incubated under these conditions in the absence of neutrophils produced significant amounts of 12-HETE and HHT, but no detectable amounts of 5-lipoxygenase products were obtained (data not shown)

The stimulating effect of added platelets on AA metabo-

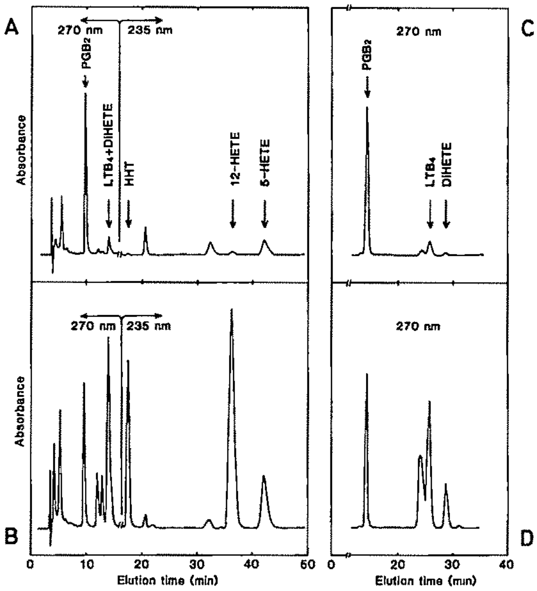

Fig 1. Reversed-phase HPLC chromatograms of AA metabolites obtained from the incubation of neutrophils with FMLP, cytochalasin B, and AA in the presence (B and D) or absence (A and C) of platelets (45 × 10^7 cells/mL). Conditions for incubation and extraction were described in Materials and Methods. The extracted products were analyzed by reversed-phase HPLC using mobile phase I (A and B) and mobile phase II (C and D) as described in Materials and Methods.

lism by platelet-neutrophil interactions depended on the ratio of platelets to neutrophils (Table 1). The production of LTB_4 and 5-HETE was increased with this ratio up to 15:1, but a further increase to 25:1 reduced the production of these metabolites. 5S,12S-diHETE generation peaked at a platelet:neutrophil ratio of 15:1. When the mixed cell suspension with the ratio of 15 to 1 was incubated with FMLP, cytochalasin B, and AA, the amount of LTB_4 produced was similar to that obtained from the incubation of neutrophils with calcium ionophore A23187 and AA (Table 1).

In experiments using mixed cell suspensions incubated with cytochalasin B and AA in the presence of varying concentrations of FMLP, the amount of LTB_4 produced was linearly increased with increasing FMLP concentrations up to 10 μmol/L, but the synthesis of 5-HETE and 5S,12S-diHETE leveled off at its lower concentration (0.1 μmol/L) (Fig 2A). In experiments with similar cell suspensions incubated with FMLP and AA in the presence of varying concentrations of cytochalasin B, 1 μg/mL or higher concentrations of cytochalasin B significantly increased LTB_4 synthesis but reduced 5S,12S-diHETE formation. No significant changes were observed in the 5-HETE formation (Fig 2B). In experiments with similar cell suspensions incubated with cytochalasin B and FMLP in the presence of various AA concentrations, the formation of LTB_4 was greatest at AA concentrations from 60 μmol/L to 120 μmol/L, 5-HETE synthesis was greatest at AA concentrations higher than 90 μmol/L, but 5S,12S-diHETE formation leveled off at 30 μmol/L AA. No 5-lipoxygenase products were consistently detectable without the addition of AA (Fig 2C).

When mixed cell suspensions were incubated with FMLP, cytochalasin B, and AA for varying periods of time, 5-HETE and LTB_4 synthesis reached a maximum within three minutes and five minutes of incubation times, respectively, and decreased thereafter, whereas 5S, 12S-diHETE synthesis reached a steady level at one- to three-minute incubations and did not decrease thereafter (data not shown).

Fig 3 shows the effect of the addition of 12-HPETE instead of platelets on the production of 5-lipoxygenase metabolites by neutrophils incubated with FMLP and AA in the presence of cytochalasin B. This unstable product from platelet lipoxygenase stimulated the production of these metabolites in a concentration-dependent manner, and the effect of 10 μmol/L 12-HPETE was comparable to that obtained when platelets and neutrophils were incubated with FMLP, cytochalasin B, and AA. In contrast, stimulation was not observed when 12-HETE, a stable end product of the platelet lipoxygenase pathway, was added to the incubation mixture at the same concentrations (up to 10 μmol/L, data not shown).

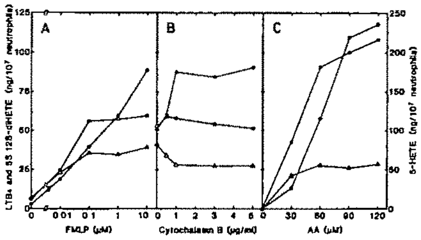

Fig 2. Effects of stimulant concentrations on the synthesis of 5-lipoxygenase products by platelet-neutrophil interactions. Cell suspensions containing neutrophils and platelets (45 × 10^7/mL) were incubated with varying concentrations of FMLP (A), cytochalasin B (B), or AA (C) as indicated in the presence of fixed concentrations of other two stimulants. The concentrations of FMLP, cytochalasin B, and AA were 10 μmol/L, 5 μg/mL, and 60 μmol/L, respectively. Products were analyzed as described in Materials and Methods. (A) and (B) were representatives of two experiments that yielded similar results, and (C) was that of three such experiments: Key: ●—●, LTB_4; ○—○, 5-HETE; △—△, 5S,12S-diHETE.

Table 2 shows the effects of platelets from MPD patients on the production of 5-lipoxygenase metabolites by neutrophils from normal donors. Lipoxygenase-deficient platelets from four patients including two each with CML and ET (patients 1 to 4 in Table 2) brought about significantly reduced production of 5-lipoxygenase metabolities by neutrophils compared with normal platelets ($P < .001$, $P < .001$, and $P < .01$ for LTB_4, 5S,12S-diHETE, and 5-HETE, respectively), whereas platelets with normal lipoxygenase activities from four patients including two with PV and one each with ET and CML (patients 5 to 8 in Table 2) activated 5-lipoxygenase similarly to platelets from normal donors. Furthermore, it was demonstrated that the 5-lipoxygenase pathway in neutrophils from a patient with platelet lipoxygenase deficiency (patient 4 in Table 2) was normally stimulated by platelets from a normal donor, although

The data were representative of three separate experiments that gave similar results. Symbols are the same as those in Fig 2.

the stimulation by this patient's platelets was reduced (Table 3).

DISCUSSION

Our experiments demonstrate that the synthesis of 5-lipoxygenase metabolites, including LTB_4, 5-HETE, and 5S,12S-diHETE, by human neutrophils was enhanced by their incubation with human platelets in the presence of FMLP, cytochalasin B, and AA and that the effect of lipoxygenase-deficient platelets on AA metabolism was significantly decreased. FMLP is a formylated peptide similar to bacterial chemotaxins and activates various neutrophil functions.[22,23] Stimulation of human neutrophils with the peptide in the presence or absence of cytochalasin B was reported to form a small amount of LTB_4[24,25] and its ω-carboxyl derivative.[26] In our experimental conditions, FMLP was considered an effective stimulant of 5-lipoxygenase metabolism since the amount of LTB_4 increased markedly with increasing FMLP concentrations up to 10 μmol/L (Fig 2A). Cytochalasin B was not essential to the consistent production of LTB_4 but augmented the effect of FMLP at concentrations of 1 to 5 μg/mL (Fig 2B) The addition of AA to the incubation mixture appeared to be essential to the activation of the 5-lipoxygenase pathway because the platelet-neutrophil mixture incubated with FMLP alone in the presence of cytochalasin B produced no detectable amount of the 5-lipoxygenase products (Fig 2C). Furthermore, there existed a critical ratio of platelets to neutrophils (15:1) in the presence of exogenous AA for the maximal LTB_4 production (Table 1).

†ng/10^7 neutrophils.

Since the 5-lipoxygenase activity has not been demonstrated in human platelets,[2,18,27] this increase in 5-lipoxygenase metabolites by platelet-neutrophil interactions was not considered a result of the conversion by the platelets themselves of AA to 5-HPETE, an unstable intermediate of the 5-lipoxygenase pathway.[1] Consumption of AA in the cell suspension medium by platelets via cyclo-oxygenase and 12-lipoxygenase pathways and liberation of AA from platelet phospholipids into the medium could occur, and they might alter the amount of this fatty acid available to neutrophils. Furthermore, platelet-derived AA has been reported to be transformed to LTB_4 and 5-HETE by stimulated neutrophils.[5] However, these possible alterations in the AA concentration in the medium could not account for the stimulating effect of platelets on the LTB_4 production since LTB_4 produced by the incubation of neutrophils with the stimulants used in our experimental system was not significantly affected by the addition of AA from 30 μmol/L to 120 μmol/L (data not shown). In our incubations, time-course studies that demonstrated the transient increase of LTB_4 lessened the possibility that platelets reduced the transformation of LTB_4 via the ω-oxidation pathway in neutrophils[26,28,29] so that LTB_4 might accumulate in the incubation mixture with a five-minute incubation. Therefore, it was

‡Platelets of this patient showed a subnormal response to thromboxane A_2 similar to our previous patient[19] (data not shown)

suggested that some platelet-derived factors other than AA per se contributed to activate the 5-lipoxygenase pathway of neutrophils.

Adenosine triphosphate and adenosine diphosphate, major constituents of platelet-dense granules, were demonstrated to activate the 5-lipoxygenase enzyme isolated from guinea pig peritoneal polymorphonuclear leukocytes.[30] However, these granule contents seemed to be of minor importance for the platelet activation of LTB_4 production by neutrophils since supernatant from washed platelet suspension in which the release reaction had been completed by thrombin showed no significant effect on the production of 5-lipoxygenase metabolities (data not shown), although the supernatant might induce production of 12S,20-dihydroxyeicosatetraenoic acid.[6] Furthermore, the use of platelets with defective release mechanisms and with normal AA metabolism prepared from patient 6 in Table 2 showed normal stimulating effects on the 5-lipoxygenase metabolism (Table 2).

Since the consistent production of 5-lipoxygenase metabolites required exogenous AA (Fig 2C), it was suggested that AA was necessary as a substrate of the 5-lipoxygenase enzyme as well as for the conversion to a metabolite with the stimulating activity by platelets. However, metabolites via the platelet cyclo-oxygenase pathway seemed to be of little significance for the platelet-induced stimulation because the addition of 500 μmol/L aspirin to the incubation mixture did not reduce the production of 5-lipoxygenase metabolites (data not shown).

The addition of 1 to 10 μmol/L 12-HPETE to neutrophils incubated with FMLP, cytochalasin B and AA stimulated the synthesis of LTB_4, 5-HETE, and 5S,12S-diHETE, whereas its stable derivative, 12-HETE, had no stimulating effect. Similar data were reported by Maclouf et al,[7] although we did not see whether 12-HPETE alone could stimulate LTB_4 production under their experimental conditions, which were different from ours. These results demonstrate an important role of 12-HPETE for the platelet-induced activation of the 5-lipoxygenase pathway during platelet-neutrophil interactions, but the activation mechanism remains to be elucidated.

Stimulating effects of platelets on AA metabolism by neutrophils were decreased when lipoxygenase-deficient platelets from MPD patients (patients 1 to 4 in Table 2) were mixed with neutrophils from normal donors. In contrast, platelets with normal lipoxygenase activities from MPD patients (patients 5 to 8 in Table 2) were no different than those of normal donors in their stimulating effect on LTB_4 synthesis during platelet-neutrophil interactions. In the case of a patient with lipoxygenase-deficient platelets (patient 4 in Table 2), the patient's neutrophils were normally activated by platelets from a normal donor and not by the patient's own platelets (Table 3); in patients with normal activities of the platelet lipoxygenase pathway, AA metabolism of the patients' neutrophils were stimulated by their own platelets in a fashion similar to that in the experiments using normal donors' platelets (data not shown). These findings also confirmed the role of 12-HPETE for the effect of platelets. Since even the lipoxygenase-deficient platelets stimulated the 5-lipoxygenase metabolism to some extent, potentiation of this metabolism by platelets may proceed through various mechanisms, only some of which involve 12-HPETE, which was studied here.

It has been suggested that LTB_4 synthesis plays an important role for some functions of neutrophils, including adhesion, chemotaxis, aggregation, lysosomal enzyme release, and generation of superoxide.[1] Therefore, our results suggest that platelets may contribute to both potentiation of inflammatory reactions and the recruitment of neutrophils to vascular lesions. Thus, synthesis of LTB_4 may play a role in thrombosis and hemostasis. It is also possible that the deficient stimulation of LTB_4 synthesis by lipoxygenase-deficient platelets from MPD patients may contribute to the high incidence of infections and vascular complications of these patients.[9]

Chemoattractant-Mediated Stimulation of the Respiratory Burst in Human Polymorphonuclear Leukocytes May Require Appearance of Protein Kinase Activity in the Cells' Particulate Fraction

By Marilyn C. Pike, Laszlo Jakoi, Linda C. McPhail, and Ralph Snyderman

Low doses of aliphatic alcohols produce divergent effects on the function of chemoattractant receptors on human polymorphonuclear leukocytes (PMNs) since they enhance chemotaxis but inhibit stimulation of superoxide production by chemoattractants. As such, alcohols can provide useful pharmacologic tools to probe the mechanisms of stimulus-response coupling in leukocytes. A role for protein kinase C has been implicated in the activation of the respiratory burst in PMNs. Although the vast majority of this enzyme activity is located in the cytosolic fraction of unactivated PMNs, protein kinase C activity appears in the particulate fraction of the cells when they are stimulated to produce superoxide by either chemoattractants or by phorbol myristate acetate (PMA). Doses of the alcohols that selectively inhibited stimulation of superoxide production by chemoattractants also inhibited the appearance of protein kinase C activity as well as an undefined protein kinase activity in the particulate fraction of the cells. In contrast, the alcohols did not affect either the ability of PMA to stimulate the production of superoxide in PMNs nor the appearance of protein kinase activity in the cells' particulate fraction. PMA is known to bind and activate protein kinase C directly, thus bypassing receptor-mediated events. These data suggest that alcohols inhibit the stimulation of the respiratory burst by chemoattractants in PMNs by blocking the ability of receptor occupancy to induce the appearance of protein kinase activity in particulate fractions. These results moreover suggest that the appearance of protein kinase activity in the particulate fraction may be required for activation of the respiratory burst in PMNs.

© 1986 by Grune & Stratton, Inc.

CHEMOATTRACTANT receptor occupancy in leukocytes results in a variety of functional responses including morphologic polarization, chemotaxis, secretion of lysosomal enzymes, and activation of the respiratory burst.[1,2] Several lines of evidence suggest that motility-related functions are regulated quite differently from secretion and superoxide production.[2,3] The concentrations of chemoattractants required to initiate the former are about 20-fold less than those required to stimulate the latter.[2,4,5] In addition, low doses of aliphatic alcohols increased the affinity of the oligopeptide chemoattractant receptor, enhanced PMN chemotaxis, yet selectively depressed chemoattractant-mediated superoxide production and lysosomal enzyme secretion.[6] The alcohols appeared to alter stimulus-response coupling by the chemoattractant receptor since superoxide release induced by phorbol myristate acetate (PMA) was unaffected.[6] Recent evidence suggests a role for protein kinase C (PKC) in superoxide production by PMNs, human monocytes, and mouse macrophage cell lines stimulated by PMA or oleoyl-acetyl glycerol.[7-10] PKC activity in unstimulated human PMNs was almost entirely cytosolic when the cells were disrupted in the presence of ethylene glycol tetra-acetic acid (EGTA), but chemoattractants and PMA induced the appearance of PKC activity in the particulate fractions.[9,11] The induction of PKC activity in the particulate fraction by chemoattractants was correlated with activation of the respiratory burst rather than with motility-related functions in that it occurred at high doses of chemoattractant and was greatly enhanced by cytochalasin B.[11] In the present work, we have used low doses of alcohols as a pharmacologic probe to determine whether superoxide release stimulated by the oligopeptide chemoattractant receptor requires the appearance of PKC activity in the particulate fractions of PMNs.

MATERIALS AND METHODS

PMA, phosphatidylserine (PS), 1,2-diolein, histone (type III), cytochrome c, cytochalasin B, f-Met-Leu-Phe (FMLP) and adenosine triphosphate (ATP) were from Sigma Chemical Co (St Louis). Gamma[^{32}P]ATP was from New England Nuclear (Boston). Trifluoperazine (TFP) and purified calmodulin were generously supplied by Drs Marty Vogel and David Sedwick, Duke University Medical Center

Cell preparation and isolation of subcellular fractions. Human blood PMNs were isolated as previously described.[12] Cells (1×10^7 in 5.0 mL) were preincubated in Hanks' balanced salt solution (HBSS) containing 10 mmol/L HEPES and 4.2 mmol/L $NaHCO_3$ (GIBCO, Grand Island, NY), pH 7.5, at 37 °C for five minutes with 10 μmol/L cytochalasin B with or without alcohols FMLP (100 nmol/L) was added for one minute or PMA (1 ng/mL to 1 μg/mL) was added for five minutes Reactions were stopped by addition of a tenfold excess of ice-cold, calcium-free HBSS containing the appropriate concentration of alcohol Cells were centrifuged, washed with alcohol-free HBSS, and the cell pellets were suspended in extraction buffer consisting of 0.05 mol/L Tris-HCL, 0 05 mol/L 2-mercaptoethanol (2-ME), 2 mmol/L EGTA, 1 mmol/L phenylmethylsulfonylfluoride (PMSF), pH 7 5,[13] and sonicated for 30 seconds at a setting of 35% using an Artek Sonic 300 Dismembranator equipped with a microtip (Artek Systems Corp, Farmingdale, NY). Following centrifugation for one hour at 100,000 g, the supernatant (cytosol) was removed and the pellet extracted with 1.0 mL of 1% Triton X-100 (Sigma) in extraction buffer. Following centrifugation for one hour at 100,000 g, the supernatant (extractable particulate fraction) was removed and the nonextractable pellet resuspended in 1.0% Triton X-100 in extraction buffer.

Assay of protein kinase C. Reaction mixtures contained 0.03 mol/L Tris-HCL, pH 7 5, 0.01 mol/L $MgCl_2$, 50 μmol/L ATP, 2×10^6 cpm [γ^{32}P]ATP, 0.4 mmol/L EGTA, 0.01 mol/L 2-ME and 0.2

mmol/L PMSF. Where indicated, 5 μg of PS, 0.5 mg of diolein, and 0.6 mmol/L $CaCl_2$ were included.[13,14] Reactions were started by adding 0.05 mL of enzyme preparation in extraction buffer containing 0.05% Triton X-100 (final reaction volume 0.25 mL) and incubated at 30 °C for five minutes for cytosolic fractions or 60 minutes for particulate fractions. The reactions were terminated with 1 mL of 25% trichloroacetic acid and 50 μg of bovine serum albumin, filtered, and counted.[14] PKC activity in cytosolic and Triton-extractable particulate fractions is expressed as pmol ^{32}P incorporated/min/10^7 cells and is given as the difference between the activity in the presence of PS, diolein, and calcium and that in the absence of these agents. A protein kinase activity present in the nonextractable particulate fraction was assayed as stated except that the PS, diolein, and calcium were not added since these substances did not affect the activity of this kinase. The concentrations of alcohols used in these studies did not affect any kinase activity when added directly to the enzyme assays (data not shown).

Assay of superoxide. Superoxide release by human neutrophils was assayed by monitoring the superoxide dismutase–inhibitable reduction of ferricytochrome c using an extinction coefficient of 29.5/mmol/L/cm as described[6] except that reaction mixtures contained 2.5 × 10^6 cells.

Determination of microviscosity parameter. Microviscosity was quantified by measuring the fluorescence polarization of diphenylhexatriene with a microviscosimeter MV-1 (Elscint, Haifa, Israel) as described previously.[6]

Table 1. Effect of Aliphatic Alcohols on Superoxide Production

Cells Incubated With*	Superoxide Release by Cells Stimulated With†		
	No Stimulant	FMLP	PMA
Buffer	0.3 ± 0.1	12.3 ± 0.6	11.1 ± 1.4
Butanol, 0.25%	0 ± 0	1.3 ± 0.5 (89%)	11.7 ± 0.2 (−5%)
Pentanol, 0.1%	0 ± 0	2.5 ± 0.6 (80%)	10.8 ± 0.4 (3%)
Isoamyl alcohol, 0.15%	0.4 ± 0	1.8 ± 0.2 (85%)	10.6 ± 0.1 (5%)

*PMNs (2.5 × 10^6) were preincubated with the indicated percentage (vol/vol) of alcohol and 10 μmol/L cytochalasin B for five minutes at 37 °C prior to the addition of stimulants.

†Cells were incubated with no stimulant, 100 nmol/L FMLP, or 1 μg/mL PMA, and superoxide release was measured for ten minutes. Superoxide release was calculated as nmol ferricytochrome c reduced/10 min/10^6 cells. Values represent the mean ± SD of duplicate determinations obtained in a representative experiment. Values in parentheses indicate percentage of inhibition. In a total of five experiments, the average percentage of inhibition by the same alcohols for FMLP was 83 ± 12, 73 ± 11, and 81 ± 6 for butanol, pentanol, and isoamyl alcohol, respectively. The alcohols produced no significant inhibition of PMA-induced superoxide release (−1 ± 1, 4 ± 4, 0.1 ± 0.3, respectively).

RESULTS

Effects of aliphatic alcohols on superoxide production and appearance of PKC in particulate fractions of PMNs. Since chemoattractants produce an increase in PKC in PMN particulate fractions,[11] we sought to determine whether this phenomenon was required for superoxide production by these agents. Cells were treated with buffer or aliphatic alcohols in the presence of cytochalasin B prior to stimulation with the oligopeptide chemoattractant FMLP or with PMA. Superoxide release was quantified in intact cells, and PKC activity was measured in subcellular fractions. Incubation of PMNs with butanol (0.25%), pentanol (0.1%) or isoamyl alcohol (0.15%) at concentrations that produced equivalent decreases in the membrane microviscosity parameter[6] (data not shown) inhibited superoxide release in response to FMLP (Table 1) by 89%, 80%, and 85%, respectively, in a representative experiment. The average inhibition of superoxide generation in five experiments with those same alcohols was 83%, 73%, and 81%, respectively. There was no significant effect on PMA-induced superoxide release. Additional experiments and previously published data[6] showed that butanol and pentanol have no effect on superoxide generation by PMA at doses of this agent ranging from 1 ng/mL to 1 μg/mL. As noted previously, FMLP did not alter PKC activity in the cytosol[11] and treatment of cells with aliphatic alcohols did not affect this (Table 2). PMA produced a profound decrease in cytosolic PKC activity, a finding that has previously been noted in PMNs and other cell types.[9,15] Butanol and pentanol enhanced the disappearance of cytosolic PKC activity produced by PMA. FMLP and PMA increased both the PKC activity found in the Triton X-100–extractable pellet and the kinase activity associated with the detergent-nonextractable particulate fraction (Table 2). Incubation of cells with the alcohols inhibited the FMLP-induced increase in PKC activity measured in both the extractable and nonextractable particulate fractions to basal or near-basal levels. In contrast, the alcohols did not significantly affect the increase in particulate fraction kinase activity produced by 1 μg/mL PMA (Table 2). The alcohols similarly did not alter the increase in this activity when submaximal doses of PMA were used (1 ng/mL to 100 ng/mL, data not shown). Table 3 shows summary data from five experiments in which the fractional stimulation of particulate fraction protein kinase activities was measured in cells incubated with buffer or the various alcohols in the presence of FMLP or PMA. Although all the alcohols diminished the increase of kinase activity induced by FMLP, in both the extractable and nonextractable fractions, they did not significantly alter PMA-induced stimulation of protein kinase activity in either particulate cell fraction.

Correlation of inhibition of FMLP-stimulated PKC redistribution with superoxide production. PMNs were incubated with buffer or with various concentrations of pentanol or butanol in the presence of cytochalasin B, and superoxide release and PKC activity in particulate fractions were measured following stimulation of the cells with FMLP or PMA. Butanol and pentanol inhibited FMLP-induced superoxide release in a dose-dependent fashion (Fig 1A). The doses of butanol and pentanol that produced 50% inhibition (ID_{50}) of superoxide were 0.16% and 0.074% respectively. In contrast, the alcohols did not alter superoxide release in response to PMA (Fig 1A). Both alcohols also produced a dose-dependent inhibition of the appearance of PKC activity in the detergent-extractable particulate fraction of PMNs in response to FMLP with ID_{50}'s of 0.11% and 0.056%, respectively, for butanol and pentanol (Fig 1B). The appearance of kinase activity in the detergent-insoluble particulate fraction of cells treated with FMLP also showed dose-dependent

*Following incubation of cells with buffer, alcohols, and/or stimulants as indicated, the cell fractions were isolated as described in Materials and Methods.

†Where indicated, cells were incubated with 100 nmol/L FMLP for 60 seconds or with 1 μg/mL PMA for five minutes. All samples contained 10 μmol/L cytochalasin B.

‡Protein kinase activity was measured in subcellular fractions of cells that had been preincubated with cytochalasin B and buffer alone or with the indicated alcohols for five minutes at 37 °C followed by exposure to buffer, FMLP, or PMA. In nonextractable particulate fractions, protein kinase activity was measured in the absence of added calcium and lipids. Results are the mean of duplicate determinations ±SD and are expressed as pmol ^{32}P incorporated/min/10^7 cells. This experiment was performed two additional times with similar results.

§Concentrations of alcohols are as follows: butanol, .025%, pentanol, 0.1%; isoamyl alcohol, 0.15%.

‖The particulate fraction was extracted with 1% Triton X-100. The soluble material is termed extractable whereas the insoluble fraction is termed nonextractable

inhibition in the presence of increasing concentrations of the alcohols with an ID_{50} of 0.078% for butanol and 0.054% for pentanol (Fig 1C). In contrast, the PMA-stimulated appearance of PKC activity in the detergent-soluble particulate fraction (Fig 1B) and that of protein kinase activity in the nonextractable subcellular fraction (Fig 1C) were not significantly affected by any of the doses of alcohols tested.

Unlike the detergent-extractable kinase, which displayed the phospholipid and calcium requirements characteristic of PKC,[16] the detergent-insoluble protein kinase activity isolated from PMNs was not dependent upon the presence of exogenously added calcium and lipid. This may be a consequence of these components remaining in the residual membrane present in these fractions. To further characterize this detergent-insoluble kinase activity, aliquots of the detergent-nonextractable material from PMA-treated cells were incubated with EGTA to establish calcium dependence or with TFP, a phenothiazine that has been shown to inhibit both PKC and the calmodulin-dependent protein kinase.[13] EGTA (1 mmol/L) inhibited the kinase activity by 62%, whereas TFP, at concentrations of 50 and 100 μmol/L, inhibited the activity by 39% and 77%, respectively (data not shown).

DISCUSSION

In several cell types including human PMNs, phorbol ester tumor promoters translocate cytosolic PKC activity to a membrane-containing fraction.[9–11,16–19] This response may be involved in tumor promotion[16–19] as well as in the activation of the respiratory burst[9–11] by the active phorbol esters. It has been shown that the active phorbol esters directly bind to PKC in intact cells, and this enzyme is therefore thought to be the receptor for these tumor promoters.[19] Chemoattrac-

Table 3. Effect of Alcohols on Particulate Fraction–Associated Protein Kinase Activity in PMNs Stimulated With FMLP or PMA

Particulate Cell Fraction*	Cells Stimulated With†	Fractional Stimulation of Protein Kinase Activity Isolated From Cells Incubated With‡			
		Buffer	Butanol§	Pentanol	Isoamyl Alcohol
Extractable	FMLP	2.7 ± 0.1	1.7 ± 0.1	1.3 ± 0.6	1.5 ± 0.2
	PMA	5.3 ± 0.6	4.7 ± 0.4	5.1 ± 0.7	6.6 ± 0.1
Nonextractable	FMLP	2.0 ± 0.1	1.1 ± 0.2	1.0 ± 0.1	1.5 ± 0.3
	PMA	6.9 ± 0.4	6.5 ± 0.7	8.0 ± 2.0	6.8 ± 1.3

*Following removal of cytosol, the particulate cell fractions were extracted with 1% Triton as indicated in Materials and Methods. Extractable and nonextractable portions were assayed for PKC activity (extractable) and protein kinase (nonextractable) activities.

†Cells were incubated with the indicated stimulant as described in the legend to Table 2.

‡Protein kinase activity was measured in particulate cell fractions of PMNs that had been treated with buffer or various alcohols and stimulated with FMLP or PMA as indicated in the legend to Table 2 and Materials and Methods. The fractional stimulation of protein kinase activity is equal to *S/C*, where *S* equals the amount of protein kinase present in particulate cell fractions of PMNs treated with FMLP or PMA and *C* is equal to that amount measured in the absence of a cellular stimulant (buffer alone). Results represent the average of five experiments ±SE.

§Concentrations of alcohols: butanol, 0.25%; pentanol, 0.1%; isoamyl alcohol, 0.15%.

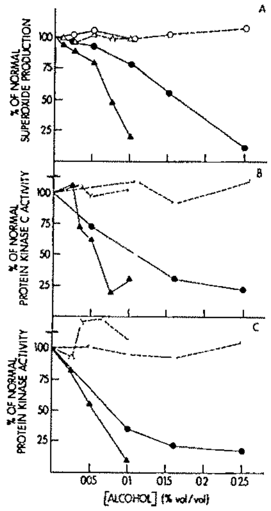

Fig 1. Dose response effects of butanol and pentanol on superoxide release (A), PKC activity in Triton X-100–extractable particulate fractions (B), and protein kinase activity in Triton X-100–insoluble particulate fractions (C) in human PMNs. Cells were preincubated with buffer and cytochalasin B alone or buffer containing butanol (circles) or pentanol (triangles) for five minutes at 37 °C followed by buffer alone or buffer containing FMLP (●, ▲) or PMA (○, △). Superoxide release was measured during a ten-minute exposure to either FMLP or PMA. Results represent the average of five experiments and are expressed as the percentage of normal FMLP- or PMA-stimulated activity in cells incubated in the absence of alcohols. The percentage of normal is calculated as *E/C* × 100, where *E* equals the activity of cells incubated in the presence of alcohols and *C* equals the activity of cells incubated in the presence of buffer alone.

tants, which stimulate superoxide production, also increase PKC activity in membrane-containing fractions of human PMNs[11]; however, chemotactic factors mediate their effects through interaction with specific cell surface receptors.[12] It can be postulated that superoxide production in leukocytes by both chemoattractants and PMA requires the activation of PKC as a component in the final common pathway leading to phosphorylation of effector proteins necessary for stimulation of the respiratory burst enzyme. To test this hypothesis, we examined the effects of aliphatic alcohols on the chemoattractant- and PMA-induced appearance of PKC activity in PMN particulate fractions. The alcohols have been shown to alter chemoattractant-mediated events at the level of the cell surface receptor, producing an increase in the affinity of the receptor, an increase in PMN chemotaxis, but a corresponding selective inhibition of chemoattractant-mediated superoxide production.[6] The present study shows that low doses of these same alcohols inhibit the FMLP-induced appearance of both PKC and the nonextractable protein kinase activity in particulate cell fractions. This effect of alcohols was dose dependent and correlated with inhibition of superoxide production. In contrast, the alcohols affected neither PMA-induced superoxide release nor enhancement of PKC activity in particulate fractions.

The protein kinase activity is the detergent-insoluble particulate fraction cannot be termed PKC since it is not stimulated by exogenously added calcium and PS. This may be due to the presence of residual lipid and calcium in the detergent-insoluble preparations. This detergent nonextractable protein kinase activity was, however, inhibited by EGTA and TFP, the latter of which is a known inhibitor of both PKC and the calmodulin-dependent, cyclic guanosine monophosphate (cGMP)-stimulated protein kinase associated with cytoskeletal fractions.[14] The insoluble kinase activity also was not stimulated further by cGMP nor by calmodulin and cGMP (data not shown), suggesting that it may be PKC in a form that does not require exogenously added Ca^{+2} or lipids. However, at this time we cannot specifically identify the kinase activity that appears in the detergent-insoluble particulate fractions of PMNs following FMLP or PMA stimulation.

The present studies suggest that stimulation of the respiratory burst in human PMNs by the chemoattractant FMLP may require the appearance of protein kinase activity in particulate fractions. We base this conclusion on the ability of the alcohols to block both the induction of the respiratory burst and the appearance of particulate-associated kinase activity mediated by chemoattractants. Indeed, NADPH oxidase, the enzyme responsible for the production of superoxide, is located in the particulate fraction of stimulated PMNs,[20] although it is not yet known if this enzyme system is directly regulated by phosphorylation. Chemotaxis is actually enhanced by doses of alcohols that inhibit the appearance of protein kinase activity in the particulate fractions[6]; so this increase in particulate fraction–associated activity is apparently not required for directed motility.

The effects of the alcohols appear to be on a chemoattractant-receptor–coupling mechanism required for activation of the respiratory burst that occurs distal to ligand binding.[6] Since the doses of alcohols used enhance the average affinity of the chemoattractant receptor as well as membrane fluidity, they could act by altering the ability of the receptor to make contact with extramembranous or transmembranous transduction units such as the guanine nucleotide regulatory unit or phospholipase C with which this receptor appears to interact.[21–25] The relationship between the affinity of the receptor and its ability to initiate the redistribution of protein kinase activity to the particulate fraction is currently unknown. However, the data suggest that the affinity state of the chemoattractant receptor reflects its ability to mediate such a redistribution of kinase activity and that this process may play a role in determining whether PMNs migrate or release cytotoxic products in response to chemoattractants.

The alcohols did not have nonspecific toxic effects since neither superoxide production nor changes in particulate fraction–associated PKC alterations induced by PMA were affected. One would not expect to see an effect of the alcohols on these PMA-induced functions since phorbol esters directly bind to and activate PKC,[19] thus bypassing the more complexly regulated receptor-coupling mechanisms operating in chemoattractant-mediated stimulation.[25–27] The apparent requirement for the appearance of kinase activity in the particulate fraction for stimulation of superoxide release suggests that subcellular redistribution of protein kinases during cellular activation leads to phosphorylation of membrane-associated proteins. This process may be a necessary step in the biochemical transduction of chemoattractant-receptor–mediated signals for activation of the respiratory burst.

T Cell Receptor Gene Rearrangements Define a Monoclonal T Cell Proliferation in Patients With T Cell Lymphocytosis and Cytopenia

By Nancy Berliner, Allan D. Duby, David C. Linch, Cornelis Murre, Thomas Quertermous, L.J. Knott,
T. Azin, A.C. Newland, D.L. Lewis, M.C. Galvin, and J.G. Seidman

We have used probes from the T cell receptor β and γ chain loci to investigate the clonality of T lymphocytes in eight patients with T cell lymphocytosis and cytopenia (TCLC). This syndrome, which is strongly associated with rheumatoid arthritis, is characterized by peripheral blood and bone marrow lymphocytosis and neutropenia, red cell aplasia, or both. By means of T cell monoclonal antibodies and flow cytometry, T lymphocytes from patients with this syndrome have been shown to have characteristic immunologic features. Investigators have disagreed as to whether the syndrome represents a T cell malignancy or a more benign immunologic disorder. DNA from five of five patients with symptomatic "classic" T cell lymphocytosis with cytopenia demonstrated unique rearrangements of the T cell receptor β chain locus, whereas neither of two patients with atypical features showed rearrangement. In addition, we found evidence for γ chain rearrangement in those DNAs with clonal β chain rearrangement. We thus postulate that the classic form of this syndrome is associated with a monoclonal proliferation of T cells. Its potential relationship to T cell chronic lymphocytic leukemia is discussed.

© 1986 by Grune & Stratton, Inc.

THE SYNDROME of T cell lymphocytosis associated with granulocyte or erythrocyte aplasia is a rare but distinct clinical entity.[1-4] Patients initially may have recurrent fever and infections associated with neutropenia or symptoms of fatigue related to anemia. Diagnosis is sometimes made by routine blood testing in asymptomatic patients There is a strong association of this syndrome with rheumatoid arthritis (RA); in the largest reported series of these patients, one third had RA.[2] Physical findings include splenomegaly, but hepatomegaly or lymph node enlargement is rare. Most patients have neutropenia, a few patients have erythrocyte aplasia, and rare patients have both. Thrombocytopenia is unusual. All patients have a peripheral blood lymphocytosis with an associated infiltration of their bone marrow with mature-appearing lymphocytes. In neutropenia, the marrow usually shows a predominance of early myeloid forms; in red cell aplasia, there may be a complete absence of erythrocyte precursors in the marrow. The course of the disease in most patients is chronic and only the minority require treatment, although some patients have died from their disease.

Previous studies have used T cell functional studies as well as monoclonal antibodies and flow cytometry to characterize the peripheral blood lymphocytes in these patients.[5-8] The T cells display a characteristic phenotype. They are CD8 (Leu2,OKT8) positive, characteristic of suppressor T cells, but they are negative, or only weakly positive, for a panel of pan-T cell CD5 markers. They also usually express the Leu7 and H366 antigens and receptors for the Fc portion of IgG, markers typically associated with natural killer cell activity.

The uniformity of the expression of these characteristic T cell antigens in the setting of the lymphocytic infiltration of the bone marrow and peripheral blood has led many investigators to postulate that this represents a monoclonal disorder related to chronic lymphocytic leukemia.[9] However, the indolent clinical course of the disease in most patients and its strong association with rheumatoid arthritis have suggested to others a more benign immunologic disorder.[2] Many of these patients have been given a diagnosis of Felty's syndrome. However, these patients can be distinguished from patients with "classic" Felty's syndrome by surface marker studies of peripheral T cells; patients undergoing splenectomy can be distinguished from those with Felty's syndrome by histologic examination of their spleens.[4]

The availability of probes for T cell receptor genes offers an opportunity to help resolve this controversy. The genes for the β chain of the T cell receptor have been cloned and have been shown to rearrange in a manner analogous to the immunoglobulin genes in B lymphocytes.[10] The immunoglobulin genes are encoded on discontinuous genes. During the course of B cell differentiation, these genes undergo rearrangement to form functional continuous genes which encode for antibody. These rearrangements are detectable by DNA blotting techniques, and rearrangement studies have been used to establish monoclonality of B cell tumors,[11] to diagnose malignancy in the face of confusing histology,[12] and to show that some classic lymphomas are in fact biclonal.[13] We have used the rearrangement of the β chain genes of the T cell receptor as a marker for monoclonality of T cells in an analogous manner. We have performed Southern blot analysis of the T cell receptor β chain genes in six patients with classic T cell lymphocytosis and cytopenia (TCLC) and in two patients with an atypical presentation. We have demonstrated unique rearrangements of the β chain genes in five of five patients symptomatic with the classic syndrome. We did not find rearrangements in a sixth patient from whom only remission blood was available or in two patients with atypical features.

*Serology only.

The γ chain genes from the mouse and from humans have also been cloned recently.[14,15] In the mouse, functional somatic rearrangement has been shown to occur primarily in cytotoxic T cells.[16] Our analysis of the DNAs from TCLC patients with β chain rearrangement showed evidence of γ chain rearrangement.

MATERIALS AND METHODS

DNA extractions were performed as described previously.[16] In brief, high mol wt DNA was prepared from spleen cells from patient 1 and from E rosette-purified peripheral blood T cells obtained from the remaining patients. When available, cells used were from patients both when they were symptomatic and when they were in remission. DNA samples from B cell lines from the same patients were used for controls. Cells were incubated overnight at 37 °C in 0.5% sodium dodecyl sulfate (SDS) and 0.2 mg/mL Proteinase K. This was followed by phenol-chloroform extraction and ethanol precipitation. DNA was digested with appropriate restriction enzymes, size-fractionated by agarose gel electrophoresis, and transferred onto nitrocellulose paper by the method of Southern.[17] Filters were hybridized to nick-translated, ^{32}P-labeled probes of the T cell receptor β and γ chain loci and washed at 55 °C in 0.1% SDS/0.15 mol/L of NaCl and 0.0015 mol/L of Na citrate prior to autoradiography.

RESULTS

Clinical profile and lymphocyte phenotype. The clinical characteristics and peripheral blood lymphocyte phenotyping of the eight patients studied have been described previously,[2] and are outlined in Tables 1 and 2. Patients 1 through 6 were considered to have had classic T cell lymphocytosis in that they had peripheral blood lymphocytosis, bone marrow lymphocytosis, cytopenia, and the typical immunologic phenotype. Blood was available in case 4 only when the patient was in clinical remission. Cases 7 and 8 were atypical in that the patients had no peripheral blood lymphocytosis but had marrow infiltration and the same T cell phenotype in their bone marrow.

Detection of T cell receptor β chain rearrangement. The organization of the β chain locus is diagrammed in Fig 1. The two constant regions (Cβ1 and Cβ2) are physically linked and lie approximately 8 kilobases (kb) from one another.[18] The probe used to analyze genomic DNA was a 1.0 kb *Bgl* II to *Bgl* II fragment from Cβ2. The two constant region genes are highly homologous in the coding region; therefore, this fragment hybridizes equally to both genes as demonstrated in Fig 1. On digestion of DNA with *Eco* RI and hybridization to the probe, two restriction fragments are predicted: a 10.8-kb fragment resulting from hybridization to Cβ1, and a 3.7-kb fragment resulting from hybridization to Cβ2. Because there is an *Eco* RI site 3′ to the Jβ2 genes, this probe will only detect rearrangements involving the joining (J) region of Cβ1. Rearrangements involving the Cβ2 genes can be detected on hybridization of the same probe to *Hind* III digests of genomic DNA. This digest results in three germline bands of 7.5, 6.5, and 3.4 kb. The first band represents hybridization to a fragment which includes the J region of Cβ2, and allows detection of rearrangements into that locus.

We detected unique rearrangements of the T cell receptor β chain in DNA from all five symptomatic patients with

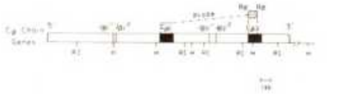

Fig 1. Organization of the human T cell receptor β chain genes. The two constant region genes (Cβ1 and Cβ2) are shown. Southern blot analysis was performed using a *Bgl* II–*Bgl* II probe from Cβ2 which hybridizes equally to both constant regions. DNA was digested with *Eco* RI or *Hind* III. The restriction sites for those enzymes are shown.

classic TCLC. Three of these cases are illustrated in Fig 2. In each case, one or more rearranged bands are seen in the DNA from patients at the time of their symptomatic illness; these bands are absent in DNAs from patients in remission (Fig 2; T cells, CR). Case 4, from whom only remission blood was available, revealed no rearrangement. The other five cases all showed rearrangement of Cβ2; only two revealed rearrangement of Cβ1. As discussed below, interpretation of Cβ1 rearrangement was hampered by the presence of a frequent unexplained band in digests of normal DNA.

The analysis of case 1 is unusual in that four rearranged bands are apparent. This is consistent with either the presence of at least two independent clones of T cells or with multiple rearrangements occurring in the same cell. The other cases were definitely consistent with a single clone of abnormal cells because the DNAs revealed only one or two rearranged bands.

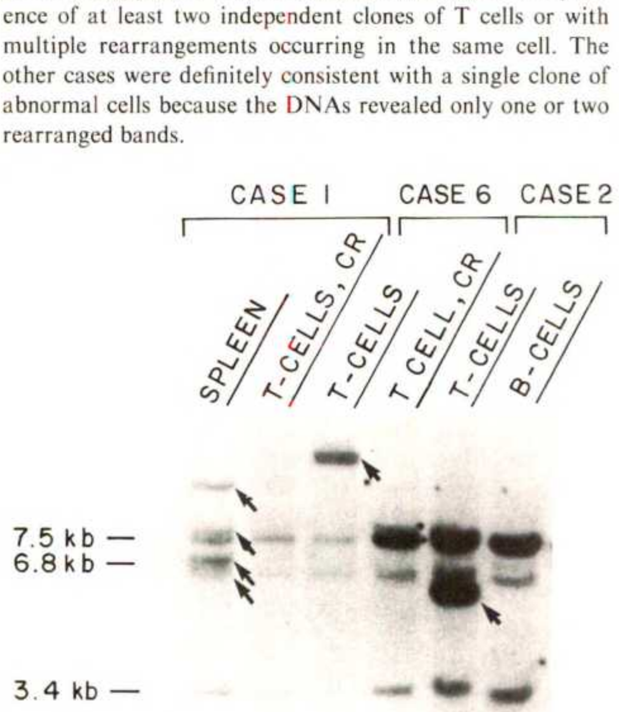

Fig 2. Evidence for β chain gene rearrangement from Southern blot analysis of DNAs from patients with TCLC. *Hind* III-digested DNAs were size-fractionated on 0.8% agarose gels and blotted on nitrocellulose as described in the Materials and Methods section. Filters were hybridized to the Cβ2 probe. Autoradiogram of three cases reveals bands indicative of somatic rearrangement of Cβ2 in all three cases. Rearranged DNA bands are indicated by arrows. Case 1 shows four discrete rearrangements, indicating a proliferation of at least two different clones. Cases 2 and 6 show evidence of a single clone, in that each sample shows only one rearranged band. In two cases, remission samples (CR) are shown and demonstrate disappearance of the monoclonal rearrangements. No remission sample was available on patient 2; a B cell line from the same patient is shown as a control.

Case 6 demonstrates the difficulty of interpreting rearrangements of Cβ1. Although this patient had a clear rearrangement of Cβ2, which in remission disappeared in the expected fashion, we noted the appearance of what appeared to be a single rearrangement of Cβ1 arising de novo in this patient in remission (Fig 3). On further analysis, we noted the frequent appearance of a similar 9-kb band, corresponding to apparent rearrangement of Cβ1, in digests of DNA from patients with unrelated disorders and in DNA from peripheral blood cells of 11 of 11 normal individuals. Minden et al observed an aberrant band in *Eco* RI digests of genomic DNAs from fibroblasts,[19] which may represent a similar finding. The DNA sequences represented by this band remain to be determined.

Detection of T cell receptor γ chain rearrangement. There are two human γ chain constant region genes.[15] We have shown that mature T cells frequently show deletion of one of the constant region genes that probably occurs in the course of somatic rearrangement of the γ chain genes.[15] DNAs from the TCLC patients were analyzed with a probe from the Cγ1 constant region to see if rearrangement of the γ chain genes, with subsequent deletion of the other gene, could be inferred from the loss of one hybridizing band on Southern blot analysis. Partial loss of one band was seen on hybridization of the γ chain probe to DNAs from patients in their symptomatic phase of the illness (Fig 4, T cells); such a deletion is not observed on analysis of DNAs from patients in remission or of DNAs from B cell lines derived from the same patients. One exception is case 1, in which there is still deletion of one of the constant region genes in DNA in remission, but no deletion in B cells. The possible significance of this will be discussed below.

DISCUSSION

The finding of discrete rearrangements of the immunoglobulin genes in B cell proliferative syndromes has been widely viewed as a marker of monoclonality and, by inference, of malignancy.[11,12] We have applied the same techniques to the examination of a T cell lymphoproliferative disorder and have shown monoclonal rearrangements of the T cell receptor genes. By analogy, we postulate that, in its classic form, TCLC usually represents a clonal expansion of a single or a limited number of T lymphocytes.

Whether this disease should consequently be labeled a "malignancy" is questionable, however. "Benign monoclonal gammopathy" is a syndrome in which a proliferation of a single clone of B cells gives rise to an abnormal circulating immunoglobulin. A small percentage of patients with this syndrome develop multiple myeloma; in the majority, however, it is clinically silent. TCLC may represent a similar disorder of T cells. However, the findings in this syndrome mimic those in B cell chronic lymphocytic leukemia (CLL) in many ways: TCLC is associated with a peripheral blood lymphocytosis, marrow infiltration with lymphocytes, and cytopenia. The finding of monoclonality in this disorder makes it highly analogous to B cell CLL and suggests that TCLC may in fact be a form of T cell CLL.

Two features make TCLC clinically distinct from CLL, however. One is the strong association with RA, a known

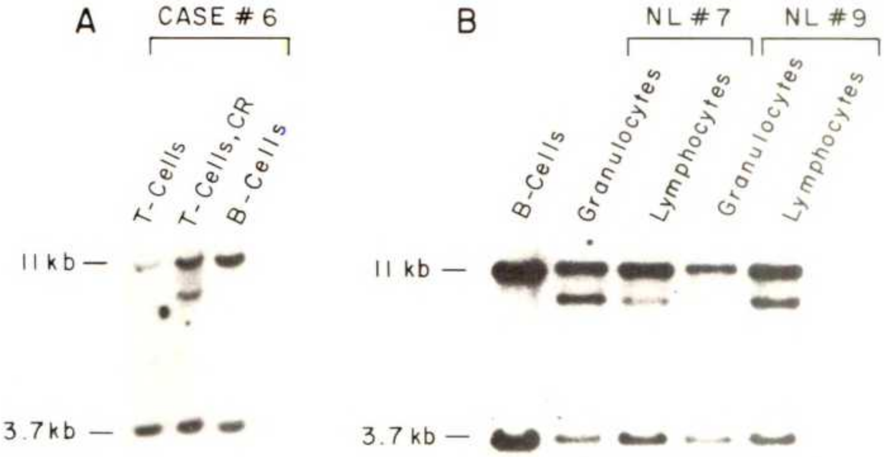

Fig 3. Presence of an aberrant band on Southern analysis of *Eco* RI digests of normal DNA. *Eco* RI-digested DNA was analyzed as explained in Fig 1. DNA from patient 6 when in remission (CR) shows a single unique nongermline band which was not present in the symptomatic (S) phase of the illness. The same band is seen on similar analysis of both lymphocytes and granulocytes from two normal individuals. It is absent in DNA from a B cell line.

autoimmune disease. The other is the observation that the syndrome is not associated with the clinical progression expected with lymphoproliferative diseases in general, and in T cell syndromes in particular. In addition, in some cases, the bone marrow is involved with similar cells, but we have been unable to detect a clonal population of peripheral blood T cells. It may be that in those cases without peripheral lymphocytosis, the clonal population is too small to detect in the peripheral blood. Alternatively, these patients may have a monoclonal population that does not have β chain rearrangement. We have not looked for α chain rearrangement in the DNAs of these patients. Finally, although these cases may simply represent a different entity, they may represent an early stage of the classic disorder from which a clonal disease may emerge. Longitudinal studies and comparisons to similar studies on patients with Felty's syndrome and patients with other autoimmune diseases may help to clarify this further.

The finding of an aberrant band on analysis of Cβ1 in normal cells is unexplained. The band may represent a true somatic rearrangement, an unexplained cross-hybridizing sequence, or an artifact. Although the significance of this finding in biological terms is not clear, in technical terms, it is extremely important to the correct interpretation of similar studies. This "normal" band may represent a large fraction of total peripheral blood mononuclear cells (in one normal individual, it appeared in equimolar concentration to the germline bands), and may be very misleading in the evaluation of gene rearrangement studies. Normal T cells from the patient, either from remission samples or from phenotypically normal cells sorted from early samples, must be used as controls for Cβ1 rearrangements. We have not noted similar stereotypic rearrangements of Cβ2, and interpretation of rearrangements involving this locus is not difficult.

The suggestion that DNA rearrangement has also occurred in the γ chain locus offers an intriguing avenue for further investigation. Although γ chain rearrangement has been shown to occur at the DNA level in all classes of T cells,[15,20] functional rearrangement leading to mRNA transcription has been shown to occur almost exclusively in murine cytolytic T cells.[20] This may help to clarify the phenotype of these cells. In vitro studies have demonstrated antibody-dependent cytotoxicity and natural killer activity[5,21] and apparent suppression of marrow growth by subsets of T cells in these patients.[6,22] This may suggest that these cells are functional cytotoxic cells that mediate the cellular aplasia characterizing this syndrome, but soluble factor inhibition cannot be excluded. Evidence of functional γ chain production by these cells would suggest that these cells are indeed cytolytic T cells and support the former contention.

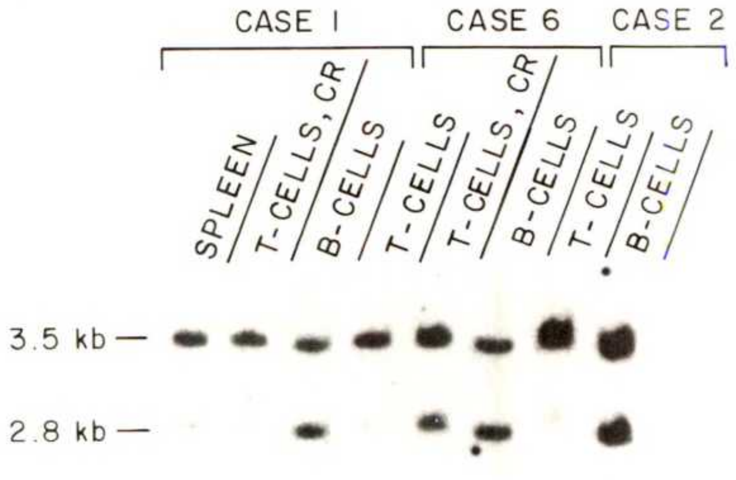

Fig 4. Evidence for γ chain rearrangement from Southern blot analysis of DNA from patients with TCLC. DNAs were digested with *Hind* III, and filters were hybridized to a probe from the Cγ1 locus, yielding two hybridizing bands of 3.5 kb and 2.8 kb in germline DNA. Samples of DNA from each patient during the symptomatic phase of illness show almost total disappearance of the 2.8-kb band, indicating deletion of one of the constant region genes. This is also seen on a remission sample from patient 1, but not on a remission sample from patient 6. DNA from B cell lines from all three patients are shown; in each case, the 2.8-kb hybridizing band is of an intensity equal to that of the 3.5-kb band, indicating a germline configuration without deletion.

Further analysis of the functionality and specificity of the unique T cell receptor gene rearrangements should help to elucidate this further.

Partial Spectrin Deficiency in Hereditary Pyropoikilocytosis

By Theresa L. Coetzer and Jiri Palek

Hereditary pyropoikilocytosis (HPP) is a severe hemolytic anemia in which an instability of the red cell membrane skeleton has been correlated with structural and functional defects of spectrin. We now report that 13 unrelated HPP subjects have ~30% less spectrin than normal as evidenced by a decreased spectrin/band 3 ratio. We also examine the role of spectrin degradation as an underlying cause of this partial spectrin deficiency. Our studies demonstrate that the reduced spectrin content of HPP red cells remains constant during in vivo aging of the cells in the peripheral blood, as well as during in vitro incubation. Furthermore, immunoblotting experiments using an affinity-purified antispectrin antibody indicate that there is no loss of spectrin during membrane preparation and also that neither whole HPP red cells nor ghosts nor cytosol contains any abnormal spectrin degradation products. These data suggest that spectrin is not degraded and that it is stable on the membrane of the circulating HPP red cell. In contrast, however, incubation of free spectrin with a lysate of nucleated erythroid precursor cells indicates that HPP α I/46 spectrin, but not HPP $\alpha^{I/74}$ spectrin, is more susceptible to proteolytic degradation than a control. These data imply that the decreased spectrin content of HPP is not due to a single defect but that a more complex mechanism is involved. In HPP Sp $\alpha^{I/46}$ subjects, an increased proteolytic degradation in bone marrow erythroid precursors of cytosolic spectrin, prior to its assembly on the membrane, could contribute toward the partial spectrin deficiency.

© *1986 by Grune & Stratton, Inc.*

HEREDITARY pyropoikilocytosis (HPP) is a relatively rare, severe congenital hemolytic anemia characterized by striking micropoikilocytosis and microspherocytosis, autosomal recessive inheritance, and a thermal instability of the red cells.[1] The red cell membrane skeleton, which consists primarily of spectrin, actin, and band 4.1, is markedly unstable in HPP subjects when subjected to shear stress.[2] This skeletal instability may be correlated with defective spectrin dimer–dimer self-association, resulting in an increased amount of spectrin dimers as opposed to tetramers or oligomers in the skeleton.[2] On a structural level, the 80,000 dalton α I domain of spectrin, which represents the dimer–dimer self-association site, is altered in HPP subjects, as evidenced by limited tryptic digestion.[3-5] On this structural basis, two subtypes of HPP may be distinguished depending on the size of the major abnormal α I peptide generated. In HPP, the normal α I 80,000-dalton domain is decreased or absent, and there is a concomitant increase in either a 74,000-dalton peptide, representing HPP Sp $\alpha^{I/74}$, or a 46,000-dalton fragment, representing HPP Sp $\alpha^{I/46}$.[3,4,6] Another feature of the HPP spectrin molecule is an increased susceptibility to thermal denaturation as measured by circular dichroism,[7] extractability,[8] and aggregation.[9]

A decrease in the amount of spectrin present in the red cell membranes of three HPP subjects has also been noted.[9,10] In this article, we confirm and extend this observation by documenting a partial spectrin deficiency in a large number of HPP patients (n = 13) and by comparing the membrane spectrin content of HPP to HE Sp $\alpha^{I/74}$ subjects and to asymptomatic carriers of HPP. In addition, we examine the role of spectrin degradation as an underlying cause of this partial spectrin deficiency in HPP. Our results indicate that the decreased spectrin content in HPP is not due to excessive degradation of the abnormal spectrin in peripheral blood, but that it may be partly due to increased proteolysis of spectrin prior to its assembly on the membrane in bone marrow erythroid precursors.

MATERIALS AND METHODS

Subjects. Thirteen HPP patients from 12 unrelated families were studied. The clinical diagnosis was based on: (a) the characteristic red cell morphology of striking poikilocytosis and microspherocytosis associated with an MCV ranging from 44 to 80 fL; (b) an increased susceptibility of the cells to thermal fragmentation and budding which occurred at 45 °C to 46 °C as opposed to 49 °C for controls; (c) an autosomal recessive mode of inheritance; and (d) an absence of identifiable abnormalities in glycolytic enzymes and hemoglobin (with the exception of patient C. E. who was homozygous for Hb C) known to be associated with nonspherocytic hemolytic anemia.[1,11] Two of the subjects (S. W. and B. S.) were white; the rest were black.

On a biochemical basis, all of the HPP subjects exhibited a marked instability of the red cell membrane skeleton when exposed to mechanical or shear stress, as well as a defective spectrin dimer–dimer self-association as evidenced by an increased amount of spectrin dimers in the membrane.[2] The proportion of spectrin dimers in the crude 4 °C spectrin extract ranged from 49% to 76% of the total spectrin dimer–tetramer pool as compared with control values of 6.0% ± 3.7% (n = 22). Limited tryptic digestion of spectrin from the HPP subjects indicated an abnormality in the α I domain of spectrin, which contains the spectrin dimer–dimer self-association site. The peptide patterns generated showed a decreased amount of the normal α I 80,000-dalton peptide and a concomitant increase in either a 74,000-dalton or 46,000-dalton peptide.[3,4] This allowed classification of the patients into subgroups and, by using the recently proposed nomenclature,[6,12] they are referred to as HPP Sp $\alpha^{I/74}$ or HPP Sp $\alpha^{I/46}$. One patient is heterozygous for both defects and is referred to as HPP Sp α I/74, 46.

The clinical and biochemical data on the hereditary elliptocytosis (HE) patients have been reported previously.[13-15] Asymptomatic carriers of HPP were identified either by the presence of an abnormal α I 74,000- or 46,000-dalton peptide or by an increased spectrin dimer content in the membrane, or both.

Venous blood was collected from the subjects, their relatives, and normal control donors in tubes containing acid citrate dextrose as

anticoagulant. The samples were cooled and transported on ice in insulated containers to Boston, where they were kept at 4 °C and analyzed either immediately or within three days.

Erythrocyte membrane preparation. Erythrocyte ghosts were prepared by hypotonic lysis at 4 °C of washed red blood cells in 3 mmol/L of $NaPO_4$, pH 8, 0.1 mmol/L of EDTA, and 0.1 mmol/L of phenylmethylsulfonylfluoride (PMSF), a protease inhibitor included to minimize proteolysis.[16] Whole cells were prepared for electrophoresis by solubilization of washed erythrocytes in 10 mmol/L of Tris HCl, pH 8, 1 mmol/L of EDTA, 5% sodium dodecyl sulfate (SDS), 5% β mercaptoethanol, and 5% sucrose, and by boiling for three minutes. Erythrocyte cytosol was obtained by lysis of washed red cells in 5 vol of lysis buffer and centrifugation at 150,000 g for 30 minutes at 4 °C. The supernatant was solubilized as described for whole cells.

Protein electrophoresis and quantitation of spectrin content. Protein samples were subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE) on 5.6% polyacrylamide gels and stained with Coomassie blue.[17] Protein concentrations were measured by the Bio Rad protein assay using bovine serum albumin (BSA) as standard. The amount of spectrin on the membrane was expressed as a ratio of spectrin to band 3 and was quantitated by densitometry of the stained gels at 540 nm and integration of the surface area under the spectrin and band 3 peaks. An alternative method of eluting Coomassie blue stain from the gel bands by 25% pyridine (vol/vol) was also used in some cases.[18]

Preparation of spectrin. Spectrin was extracted from erythrocyte ghosts by low ionic strength incubation in 0.1 mmol/L of $NaPO_4$, 0.1 mmol/L of EDTA, 0.1 mmol/L of dithiothreitol (DTT), pH 8 for 16 hours at 4 °C or for 30 minutes at 37 °C. The samples were centrifuged at 150,000 g for 30 minutes at 4 °C, and the supernatants were collected. Spectrin dimers were purified from crude control 37 °C extracts or from crude HPP 4 °C extracts by density gradient centrifugation for 16 hours at 155,000 g and 4 °C on a linear 5% to 20% sucrose gradient in either 10 mmol/L of $NaPO_4$, 20 mmol/L of NaCl, 0.1 mmol/L of EDTA, 0.1 mmol/L of DTT, and 0.1 mmol/L of NaN_3, pH 7.4 for antibody production, or in 5 mmol/L of Tris-HCl, 120 mmol/L of KCl, and 30 mmol/L of NaCl, pH 7.2, for spectrin incubation experiments.

Preparation of affinity-purified antispectrin antibody. A polyclonal antispectrin antibody was raised in New Zealand white rabbits by multiple subcutaneous injections of pure control spectrin dimers (200 to 300 μg of spectrin emulsified 1:1 with complete Freund's adjuvant) followed by two similar injections at two-week intervals with antigen in incomplete Freund's adjuvant. Serum was collected, and the antibody was affinity-purified by applying the antiserum to an Affigel 15 column (Bio Rad) containing 1 mg of spectrin per milliliter of gel. The column was washed with PBS (5 mmol/L of $NaPO_4$, 150 mmol/L of NaCl, 1 mmol/L of NaN_3, pH 7.5), and the antibody was eluted with 0.2 mol/L of glycine, pH 2.3. The fractions were immediately neutralized with $NaPO_4$, and those with the highest absorbance at 280 nm were pooled, dialyzed against phosphate-buffered saline (PBS), and stored at −20 °C.

Preparation of anti-α I spectrin antibody. The 80,000-dalton α I domain of spectrin was isolated by the procedure of Hanspal and Ralston,[19] with minor modifications. A crude low ionic strength spectrin extract was digested with TPCK trypsin (Worthington, Malvern, Pa) at 1:100 wt/wt for 20 hours at 0 °C. The digest was applied to a 1.9 × 70-cm Sepharose 4B column, and the peak containing the 80,000-dalton fragment was again concentrated and applied to a 3 × 75-mm high-performance liquid chromatography (HPLC) column of Bio Sil diethylaminoethanol (DEAE) equilibrated with 10 mmol/L of $NaPO_4$, pH 7.2. The column was developed with a gradient of 0 to 0.6 mol/L of NaCl. The 80,000-dalton α I domain obtained by this procedure was homogeneous on SDS-PAGE. A polyclonal anti-α I antibody was raised in rabbits as described above for the production of an antispectrin antibody.

Immunoblot analysis. Samples were subjected to SDS-PAGE on 5.6% or 4.5% to 15% gradient polyacrylamide SDS gels.[17] The proteins were electrophoretically transferred to nitrocellulose paper in 25 mmol/L of Tris, 192 mmol/L of glycine, 20% methanol, pH 8.3 for 20 hours at 50 V and 4 °C in a Bio Rad transblot apparatus.[20] The nitrocellulose was incubated in 20 mmol/L of Tris HCl, 0.9% NaCl, pH 7.5 (Tris-buffered saline, TBS) containing 3% BSA for 60 minutes at 22 °C. Antibody (affinity-purified antispectrin or anti-α I spectrin) was added at a dilution of 1:200 to 1:1000, and the blot was incubated for 60 minutes at 22 °C. The nitrocellulose was washed five times over a 30-minute period with TBS containing 0.05% Tween-20. A second antibody (peroxidase-conjugated goat anti-rabbit IgG, Cappel, Cochranville, Pa) was added at a dilution of 1:1000 in TBS containing 3% BSA and incubated for 60 minutes at 22 °C. The blot was washed as before and incubated with TBS containing 0.0075% H_2O_2 and 0.05% 4 chloro-1-naphthol (dissolved in methanol at 3 mg/mL, SIGMA). Development of a purple color allowed visualization of spectrin or spectrin fragments. The sensitivity of the immunoblotting technique is in the 10-ng range, which would allow detection of 0.5% of the membrane spectrin content under the experimental conditions used.

Incubation of erythrocytes. Washed erythrocytes from control and HPP subjects were suspended in 9 vol of 50 mmol/L of glycylglycine, 100 mmol/L of NaCl, 5 mmol/L of KCl, 2 mmol/L of $MgCl_2$, 2 mmol/L of $CaCl_2$, 0.5 mmol/L of adenine, 12 mmol/L of inosine, and 100 mmol/L of glucose, pH 7.4,[9,21] and incubated at 37 °C for 16 hours in a shaking waterbath. These conditions allowed the cells to maintain adequate ATP and GSH levels. After incubation, membranes were isolated, and the spectrin content was analyzed by SDS-PAGE and immunoblotting techniques as described.

Fractionation of red cells by density gradient centrifugation. Blood samples were obtained from control and HPP subjects with a high reticulocyte count (14% to 26% reticulocytes). The red cells were washed and subjected to density gradient centrifugation on 75% Percoll (Pharmacia Fine Chemicals, Piscataway, NJ). The gradients were fractionated, and each fraction was monitored for red cell morphology, percentage of reticulocytes (quantitated on brilliant cresyl blue-stained smears), glucose-6-phosphate dehydrogenase (G6PD) activity (analyzed by a Sigma kit), and spectrin content as described above.

Isolation of nucleated erythroid precursor cells. Nucleated erythroid precursor cells were isolated from the spleens of anemic rats by the method of Hanspal and Palek (M. Hanspal and J. Palek, unpublished observations and personal communication, January 1985). Anemia was induced in Sprague Dawley rats by intraperitoneal injections of 1% aqueous phenylhydrazine.[22] The rats were killed, and their spleens were placed on ice in Hanks balanced salt solution (HBSS) with no calcium or magnesium (Whittaker, M.A. Bioproducts). A cell suspension was obtained by slicing the spleens with a scalpel, disrupting the tissue with flat-tipped forceps, and then passing the fragments through a 50-mL syringe. After filtration through polyethylene gauze (Spectramesh) with a mesh size of 202 μm (Spectrum Medical Industries, Inc, Los Angeles, Calif), the cells were collected by centrifugation at 1,500 g for five minutes at 4 °C. The cells were washed twice with HBSS, resuspended and layered onto an equal volume of Ficoll-Paque (Pharmacia), and centrifuged at 800 g for 20 minutes at 4 °C to remove lymphocytes. The pellet was washed twice with HBSS and resuspended, and 1 mL of cell suspension was then layered onto 30 mL of a discontinuous Percoll gradient consisting of layers of 45%, 55%, 65%, 77%, and 90% Percoll in HBSS. The gradient was centrifuged at 5,000 g for 20 minutes at 4 °C, and cells sedimenting in the 65% and 77% Percoll layers were collected, washed twice with HBSS, and stained with benzidine/hematoxalin to identify nucleated erythroid precursor cells. White cell contamination was 2% to 4%.

Incubation of spectrin with nucleated red cell proteases. Crude 4 °C spectrin extracts as well as purified spectrin dimers were prepared from control and HPP subjects as described. The spectrin samples were incubated with freeze thawed nucleated erythroid precursors in 5 mmol/L of Tris HCl, 120 mmol/L of KCl, 30 mmol/L of NaCl, 1 mmol/L of $MgCl_2$, 0.1 mmol/L of $CaCl_2$, 1 mmol/L of DTT, 1 mmol/L of ATP, pH 7.2 at 37 °C for up to four hours. Aliquots were removed at 30, 60, 150, and 240 minutes and centrifuged at 30,000 g for 15 minutes; the supernatants were subjected to SDS-PAGE and immunoblotting techniques as described.

RESULTS

Spectrin content is diminished in HPP erythrocyte membranes. The membrane spectrin content is expressed as a spectrin/band 3 ratio and was measured by scanning densitometry of Coomassie blue-stained SDS polyacrylamide gels and confirmed by pyridine elution of the gel bands in some cases. Figure 1 shows the spectrin/band 3 ratio in normal control individuals, HPP subjects, asymptomatic carriers of HPP, and HE subjects who have the same structural (Sp $\alpha^{I/74}$) and functional (spectrin dimer–dimer self-association) defect. In control membranes, spectrin and band 3 were present in approximately equal amounts, as indicated by a mean spectrin/band 3 ratio of 1.00 ± 0.09 (mean ± SD). HE patients, as well as the carriers, had a normal spectrin content, with ratios of 0.97 ± 0.05 and 0.98 ± 0.07, respectively. In contrast, all 13 HPP patients studied have a decreased spectrin/band 3 ratio with a mean value of 0.74 ± 0.05. There was no significant difference between the various subtypes of HPP as evidenced by ratios of 0.75 ± 0.05 for HPP Sp $\alpha^{I/74}$ (n = 7), 0.72 ± 0.05 for HPP Sp $\alpha^{I/46}$ (n = 5), and 0.71 for the double heterozygote HPP Sp $\alpha^{I/74,46}$.

To rule out the possibility of spectrin loss during membrane preparation, samples of ghosts were taken at each stage of preparation and examined for spectrin content by quantitation of the spectrin/band 3 ratio. Data indicated that there was no loss of spectrin during HPP membrane preparation (not shown). Furthermore, no spectrin was present in the cytosol after lysis of the HPP cells, as evidenced by immunoblotting experiments (Fig 2).

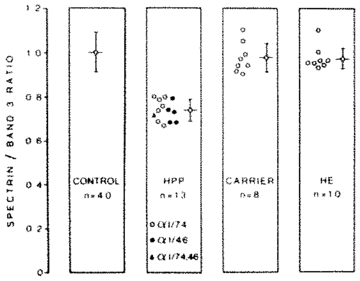

Fig 1. Spectrin content of red cell membranes. Spectrin was quantitated in membranes from control individuals, HPP subjects, asymptomatic carriers, and HE subjects with a spectrin dimer–dimer association defect by densitometry of Coomassie blue-stained sodium dodecyl sulfate-polyacrylamide gels or by elution with pyridine. The spectrin content is expressed as a spectrin/band 3 ratio; for each group, the mean value ± SD is indicated.

HPP spectrin is not degraded in circulating red blood cells. To investigate whether the decreased spectrin content of HPP red cell membranes is related to a loss of spectrin during in vivo aging of cells in the circulation, several different approaches were used. First, HPP spectrin content was correlated with red cell age by fractionating whole blood from HPP patients with a high reticulocyte count by Percoll density gradient centrifugation. Table 1 shows results of a representative experiment which indicated that the spectrin/band 3 ratio of young and old HPP Sp $\alpha^{I/46}$ red cells is similar to the ratio observed in whole blood. Similar results were obtained with HPP Sp $\alpha^{I/74}$ subjects, indicating that HPP cells of all ages are partially deficient in spectrin, suggesting that spectrin is not lost or degraded during circulating red cell maturation and that the deficiency is already manifested at the reticulocyte level.

Additional evidence for the absence of proteolytic degradation of spectrin in the circulating red cell was provided by immunoblot analysis using an affinity-purified antispectrin antibody. Figure 2 illustrates a representative SDS polyacrylamide gradient gel stained with Coomassie blue and the corresponding immunoblot of control and HPP Sp $\alpha^{I/46}$ whole cells, membranes, and cytosol. HPP Sp $\alpha^{I/74}$ subjects gave identical results (not shown). The immunoblot shows the presence of trace amounts of spectrin fragments in whole cells and membranes, visualized as faint bands below band 2, but these fragments are present in both control and HPP preparations. Furthermore, there is no evidence of spectrin or spectrin degradation products in the cytosol. These findings suggest that there is no abnormal proteolytic degradation of membrane-bound HPP spectrin, although they do not exclude the possibility that spectrin may be degraded into very small peptides not detected by the experimental procedure.

Spectrin content remains constant during in vitro red cell incubation. The HPP spectrin molecule is known to be thermally unstable[7]; during incubation at 37 °C some spectrin aggregation occurs, as evidenced by cross-linking experiments.[9] To ascertain whether this phenomenon of spectrin aggregation and denaturation contributes to the decreased spectrin content, possibly by rendering the molecule susceptible to proteolytic degradation, the spectrin content of incubated HPP red cells was examined. HPP Sp $\alpha^{I/74}$, as well as HPP Sp $\alpha^{I/46}$ cells, were incubated in vitro at 37 °C in a buffer that allowed them to maintain adequate ATP and GSH levels. Control cells in which the spectrin had been thermally denatured by heating to 49 °C for 20 minutes were also incubated under identical conditions. Table 2 shows the result of a typical experiment which indicated that the spectrin/band 3 ratio of incubated samples is the same as that found in comparable fresh cells, suggesting that spectrin denaturation does not induce degradation of the molecule and does not affect the spectrin content of the membrane.

Degradation of free HPP spectrin in erythroid precursor cells. The preceding experimental evidence indicates that HPP spectrin is stable on the membrane of the circulating red blood cell. However, nucleated erythroid precursor cells

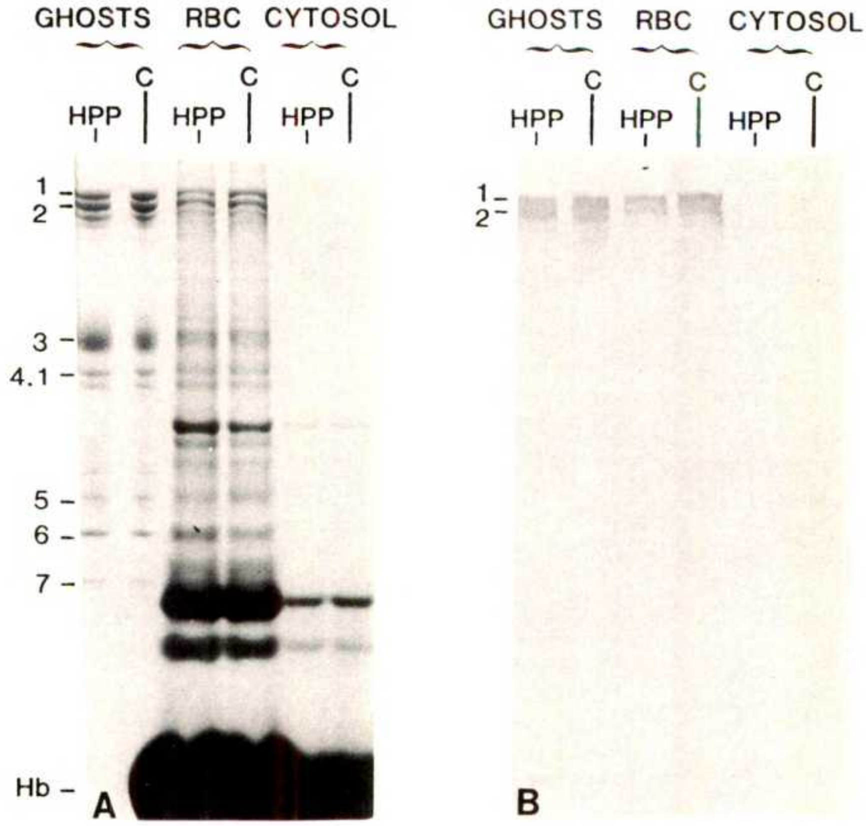

Fig 2. (A) Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and (B) immunoblots of ghosts, red blood cells, and cytosol. Proteins from control (C) and HPP Sp α I/46 ghosts, whole cells, and cytosol were subjected to SDS-PAGE on a 4.5% to 15% gradient polyacrylamide gel. Left, Coomassie blue-stained gel; right, corresponding immunoblot with affinity-purified antispectrin antibody. Trace amounts of spectrin are visualized on the immunoblot as a series of faint bands below band 2.

exhibit increased proteolytic activity[23]; therefore, the possibility that free cytosolic spectrin may be excessively degraded in bone marrow erythroid precursors, prior to its assembly on the membrane, was investigated. An in vitro experiment, using nucleated red cells from the spleens of anemic rats, was devised to test the susceptibility of free HPP spectrin to degradation by these proteases. Crude preparations of control and HPP spectrin were incubated with a lysate of nucleated red cells and, at various intervals, samples were analyzed by SDS-PAGE and immunoblotting techniques with either an affinity-purified antispectrin antibody or an antibody against the α I domain of spectrin.

Figure 3 shows representative Coomassie blue-stained gels and the corresponding immunoblots. Results showed that free HPP $\alpha^{I/46}$ spectrin, especially the α chain, was much more susceptible than control spectrin to proteolytic degradation from erythroid precursor cells. This is clearly seen in both the stained gels and the immunoblots with antispectrin and anti-α I antibodies. In contrast, free HPP $\alpha^{I/74}$ spectrin does not show any enhanced susceptibility toward degradation. Neither do purified HPP $\alpha^{I/74}$ spectrin dimers, which are enriched in the abnormal α I peptide, show any increased degradation when compared with purified control dimers (data not shown). These findings suggest that for HPP Sp $\alpha^{I/46}$ the decreased spectrin content may be partly due to increased proteolysis of free spectrin in erythroid precursor cells.

DISCUSSION

In this study, we demonstrated that red cell membranes of all 13 HPP patients studied in our laboratory were partially deficient in spectrin. The membrane spectrin content is reduced by ~30% in HPP individuals, as evidenced by a decreased spectrin/band 3 ratio. We demonstrated that this partial spectrin deficiency was not due to spectrin denaturation or proteolytic degradation in peripheral HPP red blood cells since the spectrin content did not correlate with cell age nor did it change during in vitro incubation of red cells. Furthermore, very few spectrin fragments (also present in

Table 1. Correlation of HPP Spectrin Content With Red Cell Age

Fraction No.	Reticulocytes (%)	Spectrin/Band 3 Ratio
Whole Blood	26	0.68
1	70	0.69
2	15	0.65
3	3	0.67

Results shown are representative of one of three experiments. Each value represents the mean of duplicate determinations.

Table 2. Spectrin Content During In Vitro Red Cell Incubation

	Spectrin/Band 3 Ratio	
	Fresh	Incubated (37 °C, 18 h)
Control	1.00	1.04
HPP	0.73	0.73
Heat denatured control (49 °C, 20 min)	0.95	1.00

Results shown are representative of one of three experiments. Each value represents the mean of duplicate determinations.

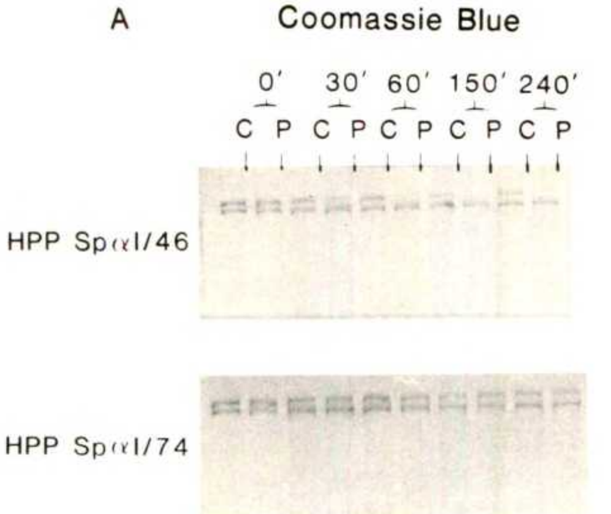

Fig 3. Degradation of spectrin by proteases of nucleated erythroid precursors. Crude spectrin from control (C), HPP Sp α I/74 (P), and HPP Sp α I/46 (P) subjects was incubated with a lysate of rat nucleated red cells for the intervals indicated. The samples were analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and immunoblotting. (A) Coomassie blue-stained SDS polyacrylamide gels; (B) immunoblots with affinity-purified antispectrin antibody; (C) immunoblot with anti α-I spectrin antibody.

control preparations) were detected in whole HPP cells or in isolated membranes, and no spectrin was present in the cytosol. These findings imply that membrane-bound spectrin is stable in circulating HPP red blood cells.

To determine whether spectrin might be prone to degradation in the bone marrow prior to the release of cells into the circulation, in vitro incubation experiments with nucleated red cell proteases were performed. Although incubation conditions did not necessarily represent the natural in vivo process, they did serve as an analogue of proteolytic conditions in the developing red cell. Results indicated that free HPP $\alpha^{I/46}$ spectrin was more susceptible than control spectrin to proteolytic degradation, suggesting that in these subjects the abnormal spectrin is degraded in erythroid precursor cells, probably prior to its assembly on the membrane; this could account for the observed partial deficiency in these individuals. In contrast, however, spectrin from HPP Sp $\alpha^{I/74}$ subjects was not excessively proteolysed when compared with control spectrin, indicating that the situation is more complex and that another mechanism contributes to spectrin deficiency in HPP. It is conceivable that an abnormality in spectrin synthesis is involved; HPP subjects may be heterozygotes for a mutant spectrin and for a variably expressed synthetic defect. This possibility is currently being evaluated in our laboratory.

ACKNOWLEDGMENT

We wish to thank all the patients and the following referring physicians for their cooperation during this study: Drs J. Prchal, L. Peterson, N. Luban, H. Cohen, W. Butler, M. Harris, G. Schewitz, R. Chilcote, C. Dampier, B. Mentzer, D. Esseltine, and V. Mankad. The anti-α I spectrin antibody was provided by Dr Jack Lawler, and Don Howard was responsible for the treatment of animals involved in this study. Mia Thurlow did the artwork, and Loretta Wencis typed the manuscript.

Aggressive Natural Killer Cell Leukemia in an Adult With Establishment of an NK Cell Line

By Louis A. Fernandez, Barbara Pope, Christine Lee, and Ekram Zayed

There have been many reports of cases in which chronic increases in the numbers of natural killer (NK) cells have been reported. Whether this is reactive or neoplastic in nature has been debated. We report the first case of an aggressive NK cell leukemia in an adult with establishment of an NK cell line. A 70-year-old man had two spontaneous episodes of jejunal perforation and one month later developed a severe febrile illness with moderate splenomegaly. Hemoglobin was 13.1 g/L, and WBC count was 1.8 × 10^9/L with 2% large granular lymphocytes (LGLs). Platelet count was 143 × 10^9/L; prothrombin time (PT) and partial thromboplastin time (PTT) were normal. Bone marrow was infiltrated with 25% to 30% LGLs; serum lysozyme was normal. Serum LDH was initially 1,191 U/L and rose to 6,408 (normal 240 to 525 U/L). Ten days later, the WBC count increased to 99.9 × 10^9/L with 70% LGL cells; the PT and PTT increased, and the platelet count dropped. No bacterial or viral cause of fever was identified. The cells from peripheral blood were LGLs that stained positively for acid phosphatase. All of the LGLs reacted with a monoclonal antibody reactive with NK cells (LEU-11b). Functionally, the patient's peripheral blood mononuclear cells (PBMs) demonstrated 100 times more lytic activity against K562 tumor cell lines than did normal PBMs. The patient's PBMs were propagated in vitro. The cultured cells showed the morphological, cytochemical, immunological, and functional characteristics of NK cells. In addition, partial trisomy involving chromosome 1q with duplication in regions of q21 through q31 was observed in all metaphases analyzed. The extra chromosome 1q with duplication in regions q21 through q31 was translocated to the p-terminal of chromosome 5. One percent to 5% of normal PBMs comprise NK cells; in most cases, leukemias arise from normal phenotypic counterparts. This case demonstrated that aggressive NK cell leukemia may occur in adults. In addition, the chromosomal abnormalities suggest that this is not a reactive process but a malignancy.

© 1986 by Grune & Stratton, Inc.

GREAT HETEROGENEITY exists among human mononuclear cells, yet in almost all cases of leukemia, normal counterparts for the phenotypic patterns of leukemia cells have been identified.[1,2] The natural killer (NK) cell is one such cell type. Normally, NK cells comprise ~3.6% of peripheral blood mononuclear cells[3] and are also present in the bone marrow and spleen.[4] Morphologically, NK cells are large granular lymphocytes (LGLs), with cytoplasmic granules that stain positively for acid phosphatase[5] and react with monoclonal anti LEU-11b.[6] The cells are identified functionally by their ability to lyse specific targets, such as the K562 tumor cell.[4] Numerous case reports have described patients with long-standing increases in the numbers of NK cells; whether this increase is reactive or neoplastic in nature has been debated.[7-9] In addition, a few cases of NK cell leukemia in children from whom cell lines have been successfully established have been described.[10-11] We believe that this is the first report of an aggressive NK cell leukemia in an adult with the establishment of a leukemia cell line that retained the morphological, immunologic, and functional characteristics of NK cells.

Most lymphomas initially exhibit infiltration of organs by a particular mononuclear cell type. In many such cases, the mononuclear cell may suddenly increase in the peripheral blood and a leukemic state is heralded. We have observed a case in which the particular cell type was identified as a NK cell. Initially, leukemic cells were present in the bone marrow, spleen, and the lamina propria of the jejunum. Within ten days, the functionally active NK cells increased in the peripheral blood. The patient became febrile, developed a bleeding diathesis, and died.

MATERIALS AND METHODS

Patient. A 71-year-old white man who had an acute abdomen was found to have a jejunal perforation. At this time, an incidental abdominal aneurysm was noted. One month later, he again developed jejunal perforation. Two months later, he was admitted to the surgical ward for repair of his aortic aneurysm. He was febrile, with a temperature of 39 °C. He had minimal cervical lymphadenopathy and moderate splenomegaly. His hemoglobin was 13.1 g/L, hematocrit .404, WBC count 1.8 × 10^9/L with 1% metamyelocytes, 6% bands, 78% polymorphonuclear cells (PMNs), 13% lymphocytes, and 2% cells that had a morphology resembling LGLs. Platelet count was 143 × 10^9/L, prothrombin time (PT) was 11 seconds, and partial thromboplastin time (PTT) was 32.2 seconds. A bone marrow aspirate showed dysplastic erythropoiesis, but was infiltrated with 25% to 30% cells that had the morphology of LGLs. Serum lysozyme was 5.7 μg/mL (normal 3.3 to 6.6 μg/mL). Serum lactic dehydrogenase (LDH) initially was 1,191; later in the course of the disease, it rose to 6,408 U/L (normal 240 to 525 U/L). EKG and chest x-ray were normal. The ultrasound showed no intraabdominal collection of fluid. Liver and spleen scan showed a normal liver and an enlarged spleen. Protein electrophoresis was relatively normal, with IgG 13.42 g/L, IgA 4.79 g/L, and IgM 0.4 g/L. Antinuclear antibody and anti-DNA was within normal limits. Viral studies, which included hepatitis antigen and antibody, hepatitis surface antigen, toxoplasma, and EBV, were negative. Blood cultures for aerobic and anaerobic organisms were negative. Because the patient was relatively neutropenic, febrile, and constitutionally ill, he was treated empirically with carbenicillin, tobramycin, metronidazole, and prednisone.

One day after admission, he developed bleeding from his gastrointestinal tract. His platelet count was 15 × 10^9/L. Both PT and PTT were more than two minutes. White cell count was 35.4 × 10^9/L, with 50% large granular LGLs. At gastroscopy, multiple gastric ulcers ranging in size from 0.5 to 2 cm in diameter were seen. There was nodularity of the mucosa. He was treated symptomatically with H_2 blockers, transfusion of fresh frozen plasma, and cryoprecipitate

without any change in the bleeding diathesis. Very rapidly, he developed generalized ecchymosis and died. Just before death, his white count had risen to 99.9 × 10^9/L, with 70% LGLs. Autopsy showed that he had infiltration of LGLs in the spleen, lymph nodes, and bone marrow. Autolytic changes made interpretation of the exact nature of infiltrating cells in the lamina propria and submucosa of the stomach and small bowel difficult. However, review of small bowel removed at initial surgery for perforation revealed that cells that were compatible with the morphology of LGL were infiltrating the lamina propria.

Morphology of cells. Peripheral blood and bone marrow slides and the cultured NK cell line were stained routinely with Wright's-Giemsa, peroxidase, Sudan Black B, periodic acid-Schiff (PAS), specific and nonspecific esterase and acid phosphatase. In addition, suspensions of PBMs and the cultured NK cell line were stained with fluorescein-conjugated monoclonal antibodies to OKT3, OKT4, OKT8, and LEU-11b antigens.[12] In brief, 5 μL of the reconstituted monoclonal antibody to OKT3, OKT4, OKT8 and LEU-11b antigens was added to 200 μL of cell suspension containing RPMI 1640 and 5% fetal calf serum (FCS). The cell suspension was mixed, placed on ice for 30 minutes, and mixed every ten minutes. The cell suspension was then washed twice with cold RPMI 1640 and resuspended in 100 μL of RPMI 1640. To this suspension was added 100 μL of fluorescein-conjugated goat anti-mouse antibody in 1:20 dilution. The suspension was mixed, placed on ice for 30 minutes, and mixed every ten minutes; it was then washed three times with cold phosphate-buffered saline (PBS). Two to three drops of buffered glycerol saline were added to the cell button, mixed and placed on a glass slide, and covered with a cover slip. Cells with fluorescence were enumerated by a Zeiss ultra violet microscope with a vertical illuminator.

In vitro establishment of NK cells. Heparinized blood from normal individuals or from our patient was diluted 1:1 with PBS and centrifuged for 30 minutes at 400 g on Ficoll-Hypaque (Pharmacia, Piscataway, NJ). The mononuclear cell fraction remaining at the interface was washed with PBS and resuspended in complete medium [RPMI 1640 medium supplemented with 10% fetal bovine serum (FBS) (GIBCO, Grand Island, NY), 100 IU/mL of penicillin, 100 μg/mL of streptomycin, 2 mmol/L of glutamine, and 5 × 10^{-5} mol/L of 2-mercaptoethanol].

Mononuclear cells from the patient were cultured in 25-cm^2 flasks (Falcon #3021, Falcon, Oxnard, Calif) in 10 mL of complete medium at an initial concentration of 10^6 cells per milliliter. In some of the cultures, the medium was supplemented with 20% T cell growth factor (TCGF). The TCGF was cultured from the cell-free supernatant of cultured rat spleen cells which had been pulsed for two hours with 10 μg/mL Concanavalin A, washed three times with PBS, and incubated for 24 hours at 5 × 10^6 cells/mL in complete medium.[13] In all cases, approximately two-thirds of the medium was replaced in the cultures three times per week. To maintain cell numbers of ~10^5 cells per milliliter, cultures were subdivided when sufficient growth occurred.

Estimation of cytotoxic activity. Cytotoxicity was estimated by chromium release assay.[14] Approximately 2 × 10^6 K562 target cells were suspended in 0.2 mL of FBS and incubated for one hour at 37 °C with 100 μCi ^{51}Cr (NEN, Lachine, Quebec). Target cells were washed three times with PBS and resuspended in complete medium at 10^5 cells per milliliter. Target cells were pipetted in 0.1-mL vol into 96-well tissue culture multitrays (#76-013-05, Flow Laboratories, McLean, Va) to give 10^4 cells per well. The effector cells were suspended in complete medium at a range of concentrations and were pipetted into the trays in 0.1-mL vol to give a range of effector-target (ET) ratios. The trays were centrifuged for five minutes at 40 g, incubated for four hours at 37 °C in 5% CO_2, and centrifuged for ten minutes at 700 g. The supernatant was removed from the cells, and 100-μL samples were counted in a Beckman Gamma 8000 counter. Maximum release was estimated as cpm from samples containing 1% Triton X-100. Minimum release was estimated in cultures containing medium alone. The percentage of lysis of the target was calculated as: sample CPM − minimum CPM/ maximum CPM − minimum CPM × 100.

Chromosome analysis. Cells cultured in TCGF-supplemented medium were harvested on the tenth day. Metaphase spreads were prepared by the conventional air-dry technique and stained according to G-banding procedures.[15]

RESULTS

Characterization of LGLs from peripheral blood, bone marrow, and established cell line. Peripheral blood LGLs were variable in size. Most of the LGLs had a low nuclear-cytoplasmic ratio and intense basophilic cytoplasm that contained prominent azurophilic granules. Relatively dense chromatin and nuclei were observed in most of these cases. Auer rods were absent, and rare vacuoles were detected (Fig 1). LGLs stained positively for both acid phosphatase and nonspecific esterase. LGLs did not express OKT3, OKT4, or OKT8 surface antigens. However, 100% of these cells stained with LEU-11b monoclonal antibody.

The cellularity of the bone marrow was moderately increased, with megaloblastic and dysplastic erythropoiesis. Granulopoiesis and megakaryocytopoiesis generally appeared normal. The pleomorphic mononuclear cells constituted 25% to 30% of all nucleated cells in the marrow. The morphology was the same as that of those seen in the peripheral blood (Fig 2). Cytochemical reactions were not conclusive; however, the LGLs stained positively for both acid phosphatase (Fig 3) and nonspecific esterase.

The cells from the established cell line had morphology and cytochemistry similar to that of the peripheral blood and bone marrow LGLs. In addition, the established cell line did not stain with OKT3, OKT4 or OKT8 antibodies. However, all of these cells stained with LEU 11b monoclonal antibody, similar to the immunologic characteristics of the peripheral blood LGL.

Growth of NK cells. PBMs from our patient maintained viability in culture for two weeks. During this time, there was no apparent difference between cultures maintained with or without growth factors. However, in the third week the cells entered a "crisis period." Cells cultured without TCGF died,

*Fresh peripheral blood mononuclear cells (PBM) or PBMs from the NK cell leukemia patient cultured with or without growth factor (TCGF) for varying lengths of time.

†Varying numbers of effector cells were mixed with 10^4 K562 target cells to give the effector-target (ET) ratios.

and cells cultured with TCGF did not proliferate. After an additional two weeks of maintenance, cells cultured in TCGF began to proliferate and were maintained for an additional two months in culture. Sufficient growth was obtained to subculture twice a week (1:3 split).

Cytotoxic assays. Table 1 shows the results of assays of the cytotoxic activity of fresh PBMs from three normal individuals and from the patient. The cytotoxic activity of PBMs of the patient was considerably higher than that seen in normal individuals. The activity of fresh PBMs from the patient at an ET ratio of 1:1 was equivalent to that seen at a ratio of 100:1 in some normal individuals. In addition, this ability to lyse K562 target cells was maintained when the patient's PBMs were cultured, and good lytic activity was seen after 60 days in culture with TCGF.

Chromosomal analysis. Twenty cells were analyzed. Partial trisomy involving chromosome 1q with duplication in regions q21 through q31 was observed in all 20 metaphases. The extra chromosome 1q with duplications in regions q21 through q31 was translocated to the p-terminal of chromosome 5 (Fig 4). The absence of the Y chromosome in 9 of 20 cells (45%) analyzed was also significant.

DISCUSSION

In this article, we provide evidence in an adult for a case of highly aggressive leukemia with the morphology and functional capability of NK cells. This conclusion was based on the finding, in the patient's blood and marrow, of abnormally high numbers of LEU-11b, $T3^-$, $T4^-$, $T8^-$, LGLs that stained positively for acid phosphatase. The conclusion that the leukemia cells were NK cells was strengthened by the finding that the patient's PBMs had a greatly enhanced ability to lyse K562 target cells. That these abnormal LGLs were malignant, rather than the result of an abnormal proliferation of NK cells, was based on the finding of chromosomal abnormalities in a cell line established from the patient's peripheral blood.

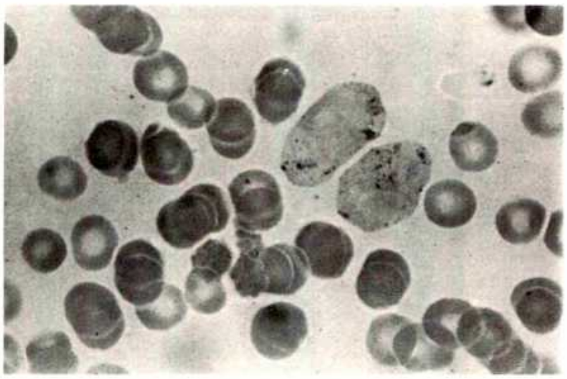

Fig 3. Acid phosphatase staining of large granular lymphocytes in peripheral blood.

In normal individuals, most NK cells are present in the peripheral blood, bone marrow, and spleen. In contrast, NK cells are rare in the lymph nodes. In animals, NK cells have also been found in the lamina propria of the small bowel.[16] Our patient initially developed jejunal perforation in a location where NK cells have been found experimentally. In addition, he had splenomegaly without lymphadenopathy; 30% of his marrow cells and, ultimately, 70% of his PBMs were LGLs.

The patient was mildly granulocytic. The cause is unknown; however, this effect may have been due to the suppressive effect of the leukemia cells. It is known that NK cells suppress granulopoiesis in vitro.[17] Most patients with chronic NK cell leukemia develop severe neutropenia, recurrent infection, and hypogammaglobulinemia. However, our patient had neutropenia without evidence of recurrent infection.

The patient developed marked swings in temperature, but no cause of infection could be found. It is now known that NK cells produce Interleukin-1, which is analogous to endogenous pyrogen.[18] Thus, the febrile response may have been due to mediator release by the NK cells, although a viral cause cannot be excluded since enhanced NK cell activity had been observed during several acute viral infections.[19,20] Although the rise in NK cells in our patient may have been secondary to a viral infection, we believe that this is unlikely because of the observed combination of high levels of LGLs

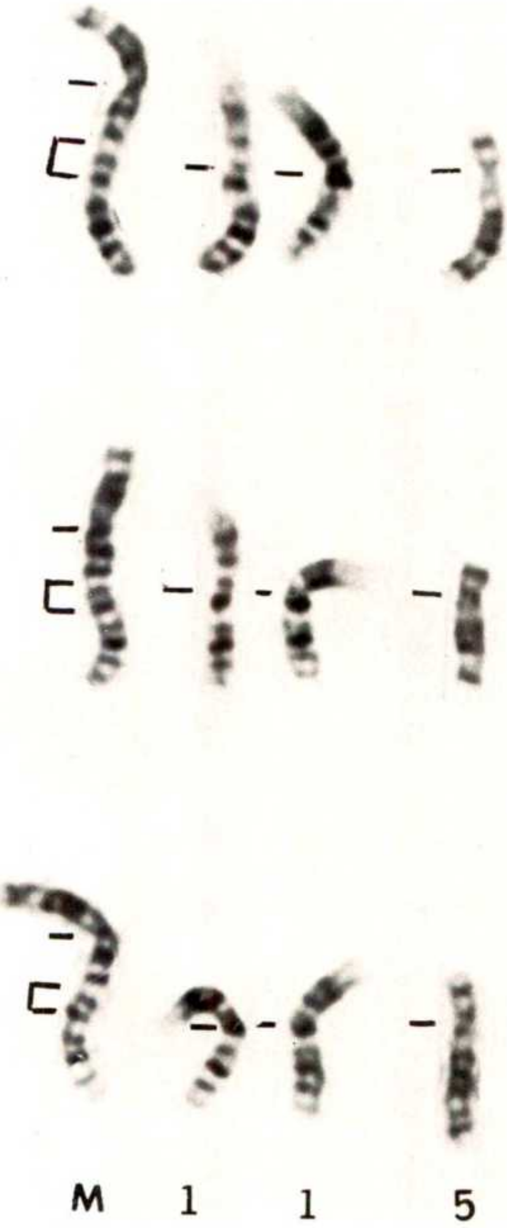

Fig 4. Partial karyotypes of three metaphases showing the marker chromosome (M), a pair of normal chromosomes (1) and a normal chromosome 5. The marker chromosome consists of chromosome 1q with duplication in bands q21 through q31 (bracket), translocated to the terminal region of the p-arm of chromosome 5. The centromere of each chromosome is indicated by a horizontal line. To compare the band pattern of the extra chromosomal material with the normal chromosomes 1q, the centromere of the marker chromosome is not aligned with the centromeres of the normal chromosomes.

in the patient's blood and marrow, enhanced lytic activity, and chromosomal abnormalities.

The coagulopathy that developed was suggestive of disseminated intravascular coagulation (DIC). DIC has been reported to occur in many malignant states, including leukemias, and is most common in acute promyelocytic leukemia.[21] However, in a few reported cases of increased NK cell activity representing either leukemia or lymphoma, DIC has not been reported.[7-11] Most cases of NK cell leukemia in adults are chronic in nature, and the disease is generally not aggressive.[22] Our case differed in its acute aggressive clinical course; in addition, our case did not express T cell antigens.

Cells with LGL morphology, with or without cytotoxic activity, have been described in patients with lymphoproliferative disorders,[8,9] in adults with chronic leukemia,[7] and in children with acute leukemias.[10,11] In some but not all cases, LGL morphology has been associated with the functional ability of the cells to lyse or bind to K562 target cells. In one case of acute leukemia, lytic activity was seen only after the incubation of the PBMs for 24 hours at 37 °C.[10,11] The PBMs from our patient not only had a high proportion of LGLs, but also displayed high, spontaneous cytotoxic activity at very low ET ratios. These results contrast markedly with those seen with PBMs from patients with lymphocytic leukemias of non-LGL morphology, in which NK cell activity has frequently been found to be depressed as compared with that of normal subjects.

Cell lines established from a child with lymphoblastic leukemia with NK activity have been previously reported.[10] These cell lines retained the surface markers and morphology of the leukemia cells, but lost much of their functional capability, having less lytic activity than that of normal PBMs. In our case, the established cell line retained the morphology, surface markers, and high cytotoxic activity of the leukemia cells seen in the fresh sample of blood from our patient. However, in both cases, the established cell lines were negative for T cell-associated surface markers and were positive for NK cell markers. The cell lines from the childhood leukemia case were negative for T3, T4, and T8, but were positive for Asialo-GM1. Both the fresh blood cells and the cell line from our patient were also negative for T3, T4, and T8, but were positive for the NK-associated marker, LEU-11b. This pattern of expression of surface markers is markedly different from that seen with most adult chronic leukemias and lymphoproliferative disorders expressing LGL morphology and NK cell activity.[7-9,22] These cells are uniformly positive for T3 and are frequently positive for T4 and/or T8. In addition, it is unlikely that the established cell line was an NK-like cell derived from a normal cell component of the patient's blood as has been reported by Brooks et al.[23] NK-like clones have been obtained from various sources including cultured cells, mixed leukocyte reactions, and cytotoxic T cell lines. However, such cell lines invariably expressed T cell-associated surface markers, even when the precursor cells were depleted of T cells prior to culture. Because our cell line never expressed T cell markers, and because the functional capability of the cells did not alter upon culture, it is most likely that the cultured cells were derived from the leukemic LGLs in the patient's blood.

Essentially all human NK cell activity is mediated by LEU-11$^+$ and LEU-7$^+$ cells although LEU-11$^+$, LEU-7$^-$ cells have the most potent lytic activity and LEU-11$^-$, LEU-7$^+$ cells have the weakest activity on a per cell basis.[6] The very potent activity seen with the cells of our patient was associated with LEU-11$^+$ cells.

Cytogenetic analysis of the cell line provided evidence that the LGL proliferation seen in this patient was a neoplastic rather than a reactive process. Cytogenetic analysis showed the presence of an extra chromosome, 1q, with duplication in regions q21 through q31 in all 20 metaphases analyzed. Although chromosomal abnormalities have been reported to arise spontaneously in vitro, they usually occur after 18 to 20 months of in vitro cell culture.[24] In our case, a 100% abnormal cell expansion of metaphases analyzed could not have arisen within ten days of culture before the cell crises occurred. Therefore, the established NK cell line was most likely derived from the leukemic NK cells in the patient. Clonal chromosomal abnormality involving the acquisition of an extra chromosome 8 or 14 was recently reported in two cases of chronic NK cell leukemia.[25] Our study documents clonal proliferation in a case of aggressive NK cell leukemia.

Partial trisomy involving the whole or part of the q-arm of chromosome 1, and in particular the duplication of regions q21 through q31, has been reported in a large variety of peripheral blood malignancies as well as in solid tumors.[26–28] Although an etiological role of this type of defect in human cancer cannot be ruled out completely, the general consensus was that abnormality involving chromosome 1q was a secondary event that was selected because it was able to confer proliferative advantage to the existing tumor cells.[29,30] Additional karyotypic changes involving the loss of a sex chromosome were observed in ~50% of myeloproliferative disorders.[31] Patients who had this additional abnormality seemed to have a poorer prognosis.[32] Almost half of the NK tumor-cloned cell population in our patient had also lost a Y chromosome.

In summary, our case demonstrates that aggressive NK cell leukemia ($T3^-$, $T8^-$, $T4^-$ and LEU $11b^+$) can develop in adults, probably arising from its normal phenotypic counterpart. These cells were established in vitro and retained their morphological, immunologic, and functional characteristics. The presence of chromosomal abnormalities suggests that this was not a reactive process but a malignancy.

Modulation of Neutrophil Oxidative Responses to Soluble Stimuli by Platelet-Activating Factor

By James C. Gay, Jeffrey K. Beckman, Karen A. Zaboy, and John N. Lukens

The role of platelet activating factor (PAF) as a regulator of human neutrophil superoxide (O_2^-) generation in response to soluble and particulate stimuli was examined. At concentrations $>10^{-7}$ mol/L, PAF alone induced a brief burst of O_2^- production. When cells were exposed to PAF and either the chemotactic peptide *n*-formyl-methionyl-leucyl-phenylalanine (FMLP 10^{-7} mol/L) or the tumor promoter phorbol myristate actate (PMA 10 ng/mL), a marked synergistic augmentation of O_2^- release was noted when compared to control cells stimulated with FMLP or PMA alone. Mean percentage of enhancement by 10^{-5} mol/L of PAF was 297% ± 35% (n = 9) of control responses to FMLP and 185% ± 16% (n = 3) of control responses to PMA. Consistent enhancement occurred with PAF concentrations of as low as 10^{-9} mol/L. Enhancement could be demonstrated when neutrophils were exposed to PAF either at the same time as, or up to 60 minutes prior to, the second stimulus, and was neither reversed by removal of PAF from the medium prior to addition of FMLP or PMA nor dependent on the presence of extracellular divalent cations. Continuous recordings revealed that the enhancement was due to an increased maximal rate of O_2^- production. In contrast, PAF concentrations up to 10^{-5} mol/L had only a minimal effect on the response to neutrophils to opsonized zymosan. Analysis of the enhancing properties of lipids structurally related to PAF revealed that the critical moiety was the saturated fatty acid at position 1. These results indicate the presence of a PAF-mediated positive feedback loop whereby the oxidative burst induced by some soluble stimuli is augmented. Modulation of neutrophil O_2^- production by PAF may serve to amplify neutrophil oxidative responses at sites of inflammation.

ACETYL GLYCERYL ether phosphorylcholine (platelet-activating factor, PAF) is a recently described lipid that is a potent activator of both platelets and neutrophils. PAF stimulates neutrophil degranulation, aggregation, oxidative metabolism, and chemotaxis.[1-5] In addition to having direct effects on neutrophils, PAF has been shown to modulate cellular responses. For example, preincubation of neutrophils with PAF causes inhibition of subsequent aggregation in response to leukotriene B_4 and to PAF itself.[6,7]

Other neutrophil stimuli, especially chemotactic factors, also modify the cell's response to other agents. For example, the chemotactic peptides formyl-methionyl-leucyl-phenylalanine (FMLP) and C5a enhance neutrophil superoxide (O_2^-) production in response to the nonchemotactic agents phorbol myristate acetate (PMA) and fluoride ion,[8] whereas they inhibit subsequent responses to higher concentrations of homologous peptides.[9] We have recently shown that leukotriene B_4 (LTB_4), a potent lipid chemoattractant and weak O_2^- agonist itself, markedly enhances the ability of neutrophils to release O_2^- in response to FMLP but does not alter oxidative responses to PMA or zymosan.[10]

PAF has potential for modulating neutrophil oxidative repsonses for several reasons. First, other agents that effect neutrophil aggregation[11] also modulate oxidative responses.[9,10] Second, like other known chemotactic factors, its chemotactic properties suggest that PAF may regulate neutrophil functions. Third, PAF elicits the production of LTB_4 by neutrophils,[12,13] and some investigators have suggested that many of the effects of PAF on neutrophils are mediated by this leukotriene.[12] Because LTB_4 enhances O_2^- production induced by FMLP,[10] PAF may possess similar properties. We have therefore studied PAF as a regulator of neutrophil O_2^- production in response to other agents. Our results indicate that PAF is a potent enhancer of neutrophil oxidative responses to soluble stimuli. These observations suggest the presence of yet another lipid-mediated positive feedback loop that may contribute to the oxidative explosion that occurs when neutrophils arrive at sites of inflammation.

MATERIALS AND METHODS

Ferricytochrome *c* (type III), zymosan, dimethyl sulfoxide, cytochalasin B, FMLP, Ficoll-Hypaque (Histopaque), superoxide dismutase (SOD), PMA, bovine serum albumin (BSA), and L-α-phosphatidylcholine, β-acetyl-γ-O-alkyl (PAF), DL-α-lysophosphatidylcholine, γ-O-hexadecyl (lyso-PAF), L-α-lysophosphatidylcholine, palmitoyl (lyso-PC), L-α-glycero-phosphorylcholine (GPC), diolein, 1-oleoyl, 2-acetyl glycerol, and 1-monopalmitoyl-rac-glycerol (monopalmitin) were purchased from Sigma Chemical Company, St Louis. Hanks' balanced salt solution (HBSS with or without calcium and magnesium) was obtained from GIBCO, Grand Island, NY. Eicosatetraynoic acid (ETYA) was a generous gift from Hoffman-La Roche, Nutley, NJ.

FMLP and PMA were dissolved in dimethyl sulfoxide at a concentration of 10 mg/mL These were further diluted in HBSS prior to use. Cytochrome *c* was dissolved in saline at a concentration of 0.8 mmol/L. SOD was dissolved in saline at a concentration of 1 mg/mL.

Zymosan was opsonized by incubation in fresh normal serum (10 mg/mL) at 37 °C for 30 minutes. The particles were then washed by centrifugation and resuspended in HBSS at a concentration of 5 mg/mL.

PAF and other lipids were stored at −4 °C in chloroform or ethanol. At the time of usage in neutrophil assays, an aliquot from the stock solution was evaporated under N_2 and redissolved in 2 5% BSA in normal saline prior to addition to the final incubation medium.

Neutrophil suspensions. Human neutrophils were isolated from heparinized venous blood from healthy adult volunteers by Ficoll-Hypaque gradient centrifugation, as previously described.[9]

Neutrophil superoxide release Superoxide (O_2^-) was assayed by measuring the O_2^--dependent (SOD-inhibitable) reduction of ferricytochrome *c*, as previously described.[14] Assays were performed in both batch and continuous fashion. All experiments were performed in triplicate and were repeated at least twice for verification. For batch experiments in which O_2^- production was measured at a single time, a suspension of neutrophils (1.5×10^6 cells) was incubated at 37 °C for ten minutes, after which PAF (or other lipid) was added to cells at the indicated concentration. Cells were then exposed to HBSS or an oxidative stimulus (FMLP, PMA, or opsonized zymosan). Incubations were continued for 5 minutes with FMLP, 10 minutes with PMA, and 10 minutes with zymosan before measurable cytochrome *c* reduction was halted by the addition of 20 μg/mL of SOD to all reaction tubes. The extent of cytochrome *c* reduction in each supernatant was determined by the change in absorbance at 550 nm (Gilford 250 recording spectrophotometer, Gilford Instrument Laboratories, Oberlin, Ohio) in reference to blanks to which SOD was added prior to any oxidative stimulus. Superoxide concentrations were calculated by means of the extinction coefficient 15.5/mmol/L per centimeter of ferricytochrome *c*[14] Results obtained in the presence of stated lipid concentrations are expressed as either nmols O_2^- per $1 5 \times 10^6$ polymorphonuclear leukocytes (PMNs) or percentage of response obtained in the absence of the lipid. Control neutrophil suspensions were preincubated with equal volumes of 2.5% BSA prior to stimulation. For experiments dealing with the influence of divalent cations on the effects of PAF, neutrophils were maintained in calcium-free and magnesium-free buffers. Indicated concentrations of these cations were added back to some reactions tubes prior to addition of PAF or its solvent.

Continuous recordings of O_2^- production were performed to assess the effects of PAF on the kinetics of O_2^- generation in response to various oxidative stimuli as previously described[15] using a Gilford 250 recording spectrophotometer. Activation time, maximal velocity (V_{max}), and cumulative absorbance at a given time were measured from the curves obtained.

Statistics. Variance is expressed as mean ± SE.

RESULTS

PAF-induced O_2^- production. As reported by others,[1,2] PAF is a direct stimulus of neutrophil O_2^- generation (Fig 1A). However, at the cell concentrations used in these studies (1.5×10^6 PMNs), only a small amount of O_2^- was released in response to PAF and only at concentrations $>10^{-6}$ mol/L. The direct response to PAF was decreased to 68% of control values when calcium and magnesium were omitted from the suspending medium (data not shown).

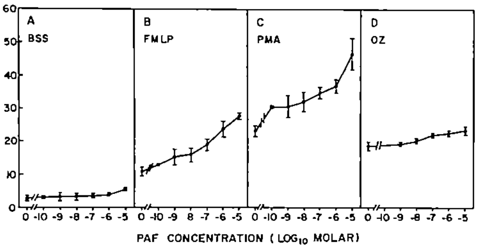

Fig 1. Effect of platelet-activating factor (PAF) on neutrophil O_2^- production. Cells were exposed to the indicated concentration of PAF immediately prior to addition of buffer or stimulus and incubation at 37 °C. (A) Hank's balanced salt solution (HBSS) for 10 minutes; (B) formyl-methionyl-leucyl-phenylalanine (FMLP), 10^{-7} mol/L for 5 minutes; (C) phorbol myristate acetate (PMA), 10 ng/mL for 10 minutes; (D) opsonized zymosan (OZ), 250 μg/mL for 10 minutes. Data points represent mean ± SE of experiments using cells from at least two donors.

Effects of PAF on neutrophil responses to other oxidative stimuli. Also illustrated in Fig 1 is the effect of PAF on neutrophil oxidative responses to FMLP, PMA, and opsonized zymosan. Responses to FMLP and PMA (Fig 1B and C) were consistently enhanced by PAF in concentration-dependent fashion. At the highest PAF concentration used (10^{-5} mol/L), enhancement averaged 297% ± 35% (n = 9) of controls for FMLP (10^{-7} mol/L) and 185% ± 16% (n = 3) of controls for PMA (10 ng/mL). Consistent slight enhancement was evident at PAF concentrations as low as 10^{-9} mol/L (143% ± 12% of controls with FMLP and 126% ± 7% of controls for PMA). The concentration of FMLP used in these experiments (10^{-7} mol/L) represents an optimal oxidative concentration of the peptide. In the presence of higher PMA concentrations, the percentage of enhancement by PAF decreased as the control response to PMA increased such that no enhancement could be demonstrated with a PMA concentration of 3.2×10^{-7} mol/L (200 ng/mL; Table 1.) Maximal absolute increase in O_2^- production seen in the presence of PAF was noted at a PMA concentration of 10 ng/mL, although the percentage of increase was greater at lower PMA concentrations. PAF, therefore, was a more potent enhancer at submaximal concentrations of the phorbol ester. The effect of PAF on the O_2^- response to FMLP and low concentrations of PMA was synergistic rather than additive. In contrast, PAF concentrations up to 10^{-5} mol/L had only a minimal enhancing effect on the response to zymosan (250 μg/mL) (Fig 1D).

Characteristics of PAF-enhanced responses. PAF enhancement of the neutrophil oxidative response to FMLP did not require incubation of neutrophils with the lipid prior to exposure to the peptide (Table 2). In our experience and that of other investigators,[1] the duration of O_2^- production in

‡Cells were exposed to cytochalasin B (5 μg/mL) for two minutes prior to addition of buffer or PAF (10^{-6} mol/L) and FMLP (10^{-7} mol/L).

§Neutrophils were incubated at 37 °C for two minutes with either buffer or PAF (10^{-6} mol/L) prior to centrifugation and two cell washings Cells were then resuspended in Hank's balanced salt solution with cytochrome *c* and exposed to FMLP (10^{-7} mol/L) for five minutes or PMA (2 ng/mL) for ten minutes at 37 °C.

response to PAF alone is brief. To determine whether the enhancing effect of PAF could be demonstrated after neutrophils had reached the plateau phase of response to PAF alone, cells were incubated with PAF for periods up to 60 minutes prior to addition of FMLP. As shown in Table 2, neutrophils exposed to PAF retained an enhanced responsiveness to FMLP even after 60 minutes of preincubation, although the effect tended to diminish with longer incubation times. Thus, PAF not only had synergistic effects with FMLP, but its enhancing effect persisted after the direct stimulating effect of PAF had reached completion. Similar effects were noted when PMA was used in place of FMLP as the secondary stimulus (data not shown).

Because we had demonstrated that optimal direct stimulation of O_2^- production by PAF was dependent on extracellular calcium, we sought to determine the calcium requirement for PAF enhancement of the response to FMLP and PMA. As noted by other investigators,[17] the response of neutrophils to FMLP was decreased in the absence of extracellular calcium (Table 3). However, in the absence of calcium, PAF-treated cells still exhibited enhanced responsiveness to the peptide, in a degree similar to enhancement seen in cells maintained in calcium-containing buffer. Enhanced responses were also noted when cells were exposed to PMA despite the absence of extracellular cations. Therefore, augmentation of FMLP-stimulated and PMA-stimulated O_2^- production by PAF did not require the presence of the divalent cation.

It is well known that the fungal metabolite cytochalasin B enhances measurable O_2^- generation in response to chemotactic peptides. The mechanism for this effect is not entirely clear but may be related to failure to internalize O_2^- produced because of impaired microfilament assembly or to aggregation or uncovering of peptide receptors.[18] Despite their already enhanced responsiveness to FMLP in the presence of cytochalasin B, neutrophils generated even greater amounts of O_2^- anion when simultaneously exposed to PAF (Table 3).

To determine whether the cellular response to PAF that resulted in enhanced responsiveness required the continued presence of PAF in the medium, neutrophils were exposed to PAF and washed twice prior to stimulation with FMLP or PMA. After being washed, PAF-treated cells continued to exhibit greater O_2^- production than did buffer-treated controls (Table 3).

Because other investigators have shown that PAF induces LTB_4 production in neutrophils,[12,13] we sought to determine whether the enhancing effect of PAF was dependent on formation of the leukotriene. As previously demonstrated[19] 10 μmol/L of ETYA, a lipoxygenase inhibitor, inhibited the response to FMLP by 59% ± 1% [FMLP alone = 16.54 ± 0.50 nmols O_2^- (n = 2); ETYA + FMLP = 6.77 ± 0.19 nmols O_2^- (n = 2)]. Despite the presence of the lipoxygenase inhibitor, PAF continued to enhance oxidative responses to FMLP (ETYA + PAF + FMLP = 33.23 ± 0.90 nmols O_2^-). Similarly, the presence of ETYA did not alter PAF enhancement of responses to PMA (data not shown). Thus, it is unlikely that the enhancing effect of PAF on neutrophils is mediated by LTB_4.

Effect of PAF on the kinetics of O_2^- production. We next examined the effects of PAF on the kinetics of the oxidative response by the continuous recording method of Cohen and Chovaniec.[15] The neutrophil oxidative response to the chemotactic peptide is characterized by a three- to six-second lag phase before O_2^- production is detected. This is followed by a progressive increase in O_2^- release which terminates three to four minutes after onset. The addition of PAF prior to addition of FMLP altered neither the activation time nor the total period of time during which the O_2^- forming oxidase was active (Fig 2). PAF-treated cells exhibited a markedly enhanced rate of O_2^- production, however, with a mean maximal rate (V_{max}) 205% ± 42% of control (n = 3). Thus, a markedly enhanced rate of O_2^- generation accounted for the augmentation of cumulative O_2^- measurements in FMLP-stimulated cells. An increase in V_{max} could be demonstrated even when PAF was added after FMLP. When PAF was added one minute after FMLP, during the time when the rate of O_2^- production is constant, the subsequent rate was increased although the total time of oxidase activity was unchanged. When PAF was added to cells two minutes after FMLP, when O_2^- production is beginning to diminish, an immediate increase in V_{max} still occurred, although the magnitude of the increase was less than when PAF was added earlier.

PAF also had striking effects on the kinetics of the response to PMA. The cellular response to PMA is characterized by a lag period prior to the onset of measurable O_2^- generation which is dependent on the PMA concentration. Figure 3 shows that when PAF was added simultaneously with PMA, the lag time was drastically shortened and the rate of O_2^- production increased markedly (mean percentage of enhancement 152% ± 11%, n = 7). When PAF was added two minutes prior to PMA, the lag time was unchanged (data not shown) although the V_{max} to O_2^- generation remained enhanced. It appears likely that the shortened activation time seen when both agents were added simultaneously is due to the direct effect of PAF, since the lag time in response to this agent is very short. When PMA was added after the direct effect of PAF was completed, the contribution of PAF to the shortened lag time was not seen. Even after preincubation of up to 20 minutes with PAF, an enhanced rate of O_2^- production was seen after addition of PMA.

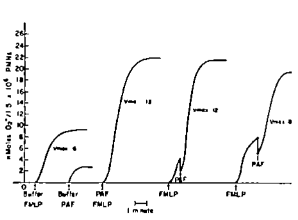

Fig 2. Continuous assays of O_2^- production in response to platelet-activating factor (PAF) and formyl-methionyl-leucyl-phenylalanine (FMLP). Neutrophils exposed to FMLP (10^{-7} mol/L) or PAF (10^{-6} mol/L) alone exhibited a brief burst of O_2^- production, which terminated after several minutes When PAF and FMLP were added simultaneously, a marked increase in rate of O_2^- production (V_{max}) was noted. A similar increase in V_{max} was noted even when PAF was added several minutes prior to FMLP (data not shown). Enhancement of V_{max} was demonstrable immediately when PAF was added either one or two minutes after FMLP. Curves represent assays performed using cells from a single donor. Similar results were obtained using cells from two different donors. V_{max}, maximal rate of O_2^- production (nmols O_2^-/min).

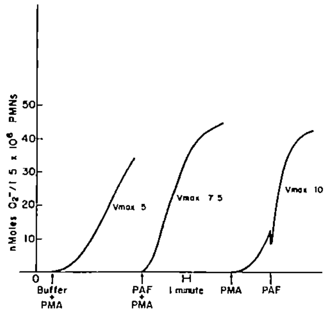

Fig 3. Platelet-activating factor (PAF) modifies the kinetics of O_2^- generation in response to phorbol myristate acetate (PMA). Neutrophils exposed to PMA (10 ng/mL) alone demonstrated approximately a one-minute lag period prior to detection of O_2^- production. When cells were simultaneously exposed to PAF (10^{-6} mol/L) and PMA, O_2^- production was detected almost immediately and the maximal rate (V_{max}) of O_2^- generation was enhanced. When PAF was added 15 minutes prior to PMA, no shortening of the lag period was seen, although the V_{max} was still enhanced (data not shown). When PAF was added after PMA, an immediate increase in V_{max} was demonstrable (V_{max} = nmols O_2^- min). Curves are representative of those obtained using cells from several different donors.

Effect of structurally similar lipids on oxidative response. To determine the specificity of PAF in enhancing O_2^- production, we studied the ability of several structurally-related lipids to enhance responses to FMLP. Because PAF consists of a glycerol backbone with an ether-linked C_{16} or C_{18} saturated fatty acid at position 1, an acetyl group at position 2, and a phosphorylcholine at position 3, we chose compounds with side chains similar to PAF in at least one of three positions. Figure 4 demonstrates dose-response curves for representative lipids. Removal of the acetyl group from position 2 of PAF yielded a compound (lyso-PAF) with 52% of the enhancing activity of PAF at 10^{-5} mol/L. Lyso-PC (substitution of a palmitoyl group for the ether-linked moiety of lyso-PAF) and monopalmitin (removal of the phosphorylcholine group from lyso-PC) had enhancing potency roughly equal to that of lyso-PAF at 10^{-5} mol/L (data not shown). Diolein, a diacylglycerol, had no significant enhancing capabilities. Neither did glycerophosphorylcholine have any effect (data not shown). In contrast, another diacylglycerol, 1-oleoyl, 2-acetyl glycerol, had enhancing activity of magnitude similar to PAF at 10^{-5} mol/L, although PAF was a more potent enhancer at lower concentrations. These results

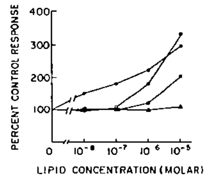

Fig 4. Enhancing effects of structurally similar phospholipids. Neutrophils (1.5 × 10^6 cells) were exposed to the indicated concentration of lipid immediately prior to addition of 10^{-7} mol/L of formyl-methionyl-leucyl-phenylalanine (FMLP) and incubation for five minutes at 37 °C. Results are expressed as percentage of O_2^- production in control cells incubated with FMLP alone. Data points represent means of experiments utilizing neutrophils from at least two different donors. PAF (●—●); Lyso-PAF (■—■); diolein (▲—▲); 1-oleoyl, 2-acetyl glycerol (○—○).

suggest that the fatty acid moiety and diacylglycerol-like activity are important components of the enhancing properties of PAF.

DISCUSSION

PAF triggers neutrophil aggregation, degranulation, and chemotaxis, and is a weak stimulus of O_2^- production. In addition to these direct effects, PAF acts as a regulator of neutrophil responses to other stimuli. Lin et al[12] have shown that PAF desensitizes neutrophils to aggregation induced by LTB_4. Jouvin-Marche et al demonstrated that PAF enhanced the O_2^- response of neutrophils to zymosan particles.[2] The degree of enhancement was consistent with an additive effect of the two oxidative stimuli, in agreement with our own studies using the same particulate stimulus. Ingraham et al[20] demonstrated that PAF enhanced oxygen uptake in neutrophils exposed to FMLP. The present studies suggest that PAF modulates neutrophil O_2^- production in response to the chemotactic peptide FMLP and the phorbol ester PMA and synergistically enhances the oxidative response to these soluble stimuli. Enhancement could be demonstrated without a preincubation period and without the presence of extracellular calcium or magnesium. It was not reversed by removal of PAF from the medium prior to FMLP or PMA exposure.

The mechanism through which PAF accomplishes enhancement remains unclear, although several potential hypotheses seem unlikely in light of our data. Because PAF stimulates LTB_4 production in neutrophils, some investigators have suggested that cellular responses to the phospholipid may be mediated by LTB_4.[12] Our demonstration that both LTB_4 and PAF enhance the oxidative response to FMLP is in keeping with this hypothesis.[10] Although an attractive explanation, it seems unlikely for several reasons. First, enhancement of the response to FMLP by LTB_4 is seen only after cells are exposed to the leukotriene for several minutes prior to addition of the peptide.[10] In contrast, no preincubation period is necessary using PAF as the enhancing agent. Second, we noted marked augmentation of the response to PMA in PAF-treated cells, whereas LTB_4 had no effect on the response of cells to the phorbol ester.[10] Third, the lipoxygenase inhibitor ETYA did not eliminate PAF-mediated enhancement. Thus, it seems likely that PAF exerts its enhancing effect on neutrophil O_2^- production by a mechanism independent of the generation of LTB_4. Alternatively, it is possible that enhancement is mediated by an increase in cellular uptake of calcium. The finding that enhancement of FMLP-induced and PMA-induced oxidative responses by PAF occurred even in the absence of extracellular Ca^{2+} suggests that the mechanism of PAF enhancement does not involve transport of Ca^{2+} into the cell. From our data, however, we cannot rule out an effect on intracellular Ca^{2+} metabolism which could result in a heightened response to soluble stimuli.

It has been shown that preincubation of neutrophils with any of a number of oxidative stimuli results in potentiation of subsequent responses to heterologous oxidative stimuli.[8,10,21] McPhail et al[21] studied this phenomenon and described the cellular response to the first stimulus as "priming." These authors suggested that although oxidative stimuli differ in the transductional mechanisms, they share a common intermediate pathway. One attractive intermediate is protein kinase C, which is activated during neutrophil stimulation by several oxidative stimuli.[22-24] Such stimuli may act through protein kinase C-mediated phosphorylation of neutrophil proteins involved in the generation of O_2^-. A priming stimulus may activate protein kinase C in such a way that response to a second stimulus also working through the kinase is augmented. PAF may be another primary oxidative stimulus acting through this intermediate to enhance responses to other stimuli. In our studies, 1-oleoyl, 2-acetyl glycerol, a diacylglycerol known to stimulate protein kinase C activity, also enhanced O_2^- production, in agreement with a recent report by DeWald et al.[25] Therefore, it is also possible that the enhancing effect of PAF is also mediated through the kinase. Our failure to demonstrate enhancement with diolein, a long-chain diacylglycerol, is consistent with reports showing that this compound does not activate protein kinase C in intact cells, presumably because of the lipid's inability to intercalate into the plasma membrane.[26]

The priming effect of PAF appears to be virtually instantaneous, as shown by continuous assays of O_2^- generation. Such rapid responses may be mediated through direct effects on the neutrophil plasma membrane. The fact that many lipids, including lyso-PC (structurally similar to PAF) are detergents suggests that PAF may also have detergent-like properties. Such properties may alter membrane configuration in such a way that the activity of the O_2^--forming NADPH oxidase system is augmented.

PAF is produced by activated neutrophils and thus may be present in extracellular fluid in inflammatory foci. The lipid may serve to increase oxygen metabolite release at these sites, potentially enhancing both the microbicidal and tissue-damaging properties of neutrophils. The modulation of neutrophil O_2^- generation by PAF is just one of many described instances of regulation of the oxidative response. These regulatory points, whether they be enhancing or inhibitory, provide multiple checks and balances on the inflammatory response. Such mechanisms ensure that this potent immunologic weapon can be held in check until the time when the rapid, powerful neutrophil metabolic burst offers maximal benefit to the host.

B Cell Growth Factor-Induced Proliferation of Hairy Cell Lymphocytes and Inhibition by Type I Interferon In Vitro

By Kathryn A. Paganelli, Sharon S. Evans, Tin Han, and Howard Ozer

Malignant B cells from hairy cell leukemia (HCL) patients are unable to proliferate when stimulated with standard B cell mitogens. Using chromatographically purified B cell growth factor (BCGF), HCL can be stimulated to proliferate as assessed by incorporation of tritiated thymidine (^{3}H-TdR) into DNA. Proliferation was found to be time dependent, with no detectable ^{3}H-TdR incorporation in up to three days of culture, and significant stimulation evident at days 6 and 10. The presence of 10% BCGF in culture was an absolute requirement for HCL proliferation; however, this BCGF-induced DNA synthesis could be further augmented by the addition of anti-immunoglobulin heavy chain antibodies. BCGF-induced proliferation was abrogated in six of six patients by addition of 1,000 U/mL of recombinant α_2-interferon (IFN) at day 0, although 1,000 U/mL of recombinant γ-IFN had no inhibitory effect in five of six patients studied. Specific cellular receptors for type I IFN were demonstrated in HCL by inhibition of binding of ^{125}I-α_2-IFN by a 40-fold excess of unlabeled α_2 or β IFN with no inhibition by unlabeled γ-IFN. These data demonstrate that malignant HCL lymphoblasts express specific type I IFN receptors and that type I, but not type II IFN, can inhibit growth factor-induced DNA synthesis by hairy cells in vitro. They further suggest a direct antiproliferative mechanism of action for IFN in HCL and predict equivalent clinical activity by either α or β, but not γ IFN in this malignancy.

© 1986 by Grune & Stratton, Inc.

ALTHOUGH there has been a great deal of controversy over the origin of the malignant cell in hairy cell leukemia (HCL), recent evidence presented by Korsmeyer et al demonstrates unequivocally that hairy cells have immunoglobulin gene rearrangements characteristic of B cells,[1] providing a convincing argument for the B cell origin of the HCL cell at the genetic level. Among the restrictions imposed in elucidating the biology of this leukemia is the fact that hairy cells are relatively unresponsive to induction of proliferation by standard B cell mitogens.[2,3] Reports on the ability of mitogen-stimulated T cell supernatants and purified B cell growth factor (BCGF) to stimulate normal[4-8] and leukemic[9] human B cells to proliferate in short-term and long-term culture led us to test BCGF on malignant HCL B cells to determine whether this growth factor would support their growth and proliferation. We report here data demonstrating that chromatographically purified BCGF induces proliferation of hairy cells in short-term culture as determined by tritiated thymidine incorporation, and that anti-immunoglobulin heavy-chain antibodies can further augment this response.

The low proliferative index of HCL cells with standard B cell mitogens has previously hindered in vitro studies on hairy cells, especially in terms of cytogenetic analysis and determination of antiproliferative drug effects. In response to recent reports of dramatic clinical remissions induced by α-interferon (IFN) therapy in HCL,[10,11] we used BCGF-induced HCL proliferation to examine first the direct effects of types I and II recombinant IFN on the proliferative response of HCL cells to BCGF, and second the expression and specificity of IFN receptors on HCL cells. Although previous studies of IFN receptor expression have been performed almost exclusively on lymphoblastoid[12-15] and fibroblast[16] cell lines, the data presented here support the contention that HCL cells express specific type I receptors and that binding of recombinant α-IFN to these receptors can directly inhibit growth factor-induced DNA synthesis in this malignancy.

MATERIALS AND METHODS

Reagents. BCGF was obtained from Cellular Products, Inc, Buffalo. This factor has been chromatographically purified from crude mitogen-stimulated peripheral lymphocyte supernatants and is devoid of interleukin 2 (IL-2) activity but capable of sustaining the growth of normal B lymphocytes. Polyclonal rabbit anti-human μ and γ chain antibodies coupled to polyacrylamide beads were purchased from Bio-Rad Laboratories, Rockville Centre, NY. Recombinant α_2-IFN was obtained from Schering Plough Corporation, Kenilworth, NJ; β-IFN was obtained from Cetus Corporation, Emeryville, Calif; and γ-IFN was obtained from Biogen Inc, Cambridge, Mass. All interferons (α_2, β, and γ) were recombinant bacterial products purified to > 99% homogeneity

Preparation of affinity-purified rabbit anti-human IgM (soluble anti-μ). Pure IgM was obtained by passage of the ammonium sulfate-precipitated immunoglobulin fraction of an IgM macroglobulinemia patient's serum over a Sephacryl-200 (Pharmacia Fine Chemicals, Piscataway, NJ) column. Recovered IgM was determined to be free of IgG and IgA by ELISA and sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). This IgM was used to immunize a rabbit to human IgM and to couple to an affinity column for recovery of anti-IgM. The affinity column was prepared by coupling IgM to cyanogen-bromide–activated Sepharose-4B (Pharmacia) according to manufacturer's directions. The IgM-coupled gel was packed into a 3-mL syringe, and serum from the IgM-immunized rabbit was recirculated through the gel overnight at room temperature by means of a peristaltic pump The syringe was washed with at least 10 bed vol of phosphate-buffered saline (PBS), and the coupled anti-human IgM was eluted with 0.1 mol/L of glycine HCl containing 1 mol/L of NaCl (pH 2.5). The eluted fractions were pooled and dialyzed against PBS. Any reactivity to IgG was removed by absorbing the anti-IgM eluate with IgG coupled to Sepharose-4B.

Cell separation. Eight patients with HCL in leukemic phase were used as peripheral blood donors for these studies. All were men,

ranging in age from 37 to 75 years. Mononuclear cells were separated from heparinized blood samples by Ficoll-Hypaque density gradients. Recovered cells were washed and resuspended in RPMI 1640 medium supplemented with antibiotics, 25 mmol/L of HEPES buffer and 20% fetal calf serum (FCS) This cell population was T cell depleted by rosetting overnight at 4 °C with AET-modified sheep red blood cells (SRBCs).[17,18] Nonrosetting cells (hereinafter referred to as B cells) were removed from the interface of a second Ficoll gradient. The percentage of hairy cells in this population was routinely assessed by morphological examination of cytocentrifuge preparations stained with Wright's-Giemsa. Staining for tartrate-resistant acid phosphatase (TRAP) was also performed on duplicate slides.[19] Latex bead ingestion[20] was determined by incubating 1×10^6 cells with 10 μL of a 1:10 dilution of 1.1-μm latex particles (Sigma Chemical Co, St Louis, LB-11) in a final 1 mL vol. After a one-hour incubation at 37 °C in a humidified atmosphere of 5% CO_2 in ambient air, cells were washed and cytocentrifuge preparations were made. Slides were stained with Wright's-Giemsa, and cells ingesting two or more latex particles were assessed as positive for phagocytic activity.

Normal human B cells were isolated from buffy coats as follows. peripheral blood buffy coat concentrate was withdrawn from a sterile transfer pack into a heparinized syringe and centrifuged for 30 minutes at 1,500 rpm over a Ficoll gradient. Mononuclear cells from the interface were depleted of adherent cells by incubating them for one hour at 37 °C in a 30-mL vol of RPMI 1640/10% FCS in a 75-cm^2 plastic flask (Corning 25110). The nonadherent cells were poured off, washed, and subsequently depleted of T cells by AET-SRBC rosetting for 90 minutes on ice. After Ficoll separation, the T-depleted lymphocyte population was put through a second one-hour adherence step at 37 °C and a second rosetting step at 4 °C for 18 hours. After removal of rosetted T cells by Ficoll, the resulting population was used as the source of normal B cells

Proliferation assay for HCL B cells and normal B cells. Cultures were performed in 96-well flat-bottomed microtiter plates (Corning 25860) with 1×10^5 cells per well in a 0.2-mL vol. Factors were added to cultures as described in legends to Figs 1 through 5. Incubations for indicated time periods were carried out at 37 °C in a humidified 5% CO_2–air atmosphere; 2 μCi per well of methyl-^{3}H-thymidine (6.7 Ci/mmol) (New England Nuclear, Boston) were added, and harvesting of cells onto glass microfiber filters was performed 24 hours later. Filters were placed in scintillation vials containing 7 mL of a mixture of 170 mL of Spectrafluor PPO-POPOP (Amersham Corporation, Arlington Heights, Ill) to 4 L of toluene (J.T. Baker Chemical Co, Phillipsburg, NJ) and counted in a beta scintillation counter (Tri-Carb 460 C, Packard Instrument Co, Inc, Downers Grove, Ill).

TCGF assay. BCGF was confirmed to be free of IL-2 activity by both a thymidine incorporation assay and a five-day growth assay, comparing BCGF with a TCGF standard for activity on activated T cells.

Target T cells were prepared by a seven-day activation of human peripheral lymphocytes prepared from Ficoll-separated buffy coats. T cells were stimulated with 0.5% vol/vol phytohemagglutinin-p (PHA-P) (Difco Laboratories, Detroit) in RPMI 1640 containing 15% FCS and 50 μg/mL of gentamycin at a cell density of 1×10^6/mL. Cultures were held at 37 °C for seven days, at which time activated T cells were recovered and washed three times in RPMI 1640.

Thymidine incorporation was assessed by placing 1×10^5 activated cells per well in a 96-well plate along with twofold dilutions of either BCGF or a TCGF standard, beginning at 25% concentration of factor. Cells were diluted in RPMI 1640 containing 15% FCS, 50 μg/mL of gentamycin, and 2 mmol/L of glutamine. After 48 hours of incubation at 37 °C, cultures were pulsed with 0.25 μCi of tritiated thymidine per well and were harvested after 24 hours

Five-day growth assays were carried out, using the same population of activated T cells: 2×10^5/mL T blasts were placed in 1-mL aliquots in 24-well trays with final concentrations of 0% to 20% BCGF or TCGF standard. Cultures were counted after five days at 37 °C and compared with the TCGF standard.

Iodination of α_2-IFN. Iodination was carried out by the iodogen method, essentially as described by Markwell and Fox.[12] In brief, 10 μg of α_2-IFN (5×10^4 U) were combined with 0.5 mCi of Na ^{125}I in a 30-μl vol and allowed to react for 30 minutes at room temperature. Free ^{125}I was separated from bound ^{125}I by fractionation on a Sephadex G-25 column. The radioactive peaks were pooled and tested for antiviral activity by challenge of GM2504 cells with vesicular stomatitis virus, with assessment of protection from viral cytopathic effect according to Finter's method. α_2-IFN was iodinated to a final specific activity of 32 mCi/mg of protein and retained >90% of its antiviral activity.

Cellular binding of ^{125}I-α_2-IFN. Specific binding of ^{125}I-α_2-IFN to hairy cells was performed by modification of the method of Branca and co-workers.[14,15] In brief, 5×10^6 or 1×10^7 cells were incubated in plastic 12 × 75-mm tubes (Falcon, Oxnard, Calif) with 0 5 to 50 ng of ^{125}I-α_2-IFN in a final 1-mL vol of RPMI 1640/20% FCS for one hour in a 37 °C water bath. Duplicate tubes containing a 40-fold excess of unlabeled α_2-IFN in addition to the labeled IFN were included to quantitate nonspecific binding. Unbound ^{125}I-α_2-IFN was removed by three washes with 0.1% BSA/PBS, and the dry cell pellets were counted in a Packard model 5260 gamma counter. Specificty of binding was determined by the formula. percentage of specific binding = uninhibited CPM − inhibited CPM/inhibited CPM × 100.

RESULTS

Cell populations. HCL B cells (E rosette negative) in all cases were > 90% typical HCL cells by morphological criteria. TRAP positive cells in these populations ranged from 4% to 82%, and latex phagocytizing cells ranged from 33% to 92%.

Thymidine incorporation of peripheral blood HCL B cells. As seen in Fig 1, BCGF stimulated thymidine uptake of HCL cells in a time-dependent manner. No thymidine was

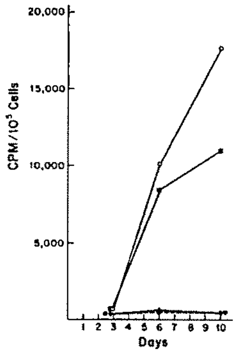

Fig 1. ^{3}H-Thymidine incorporation by hairy cell leukemia (HCL)-B cells. E rosette-negative cells were incubated for 3-, 6-, and 10-day periods with medium alone (RPMI 1640/20% fetal calf serum), 10% B cell growth factor (BCGF), 15 μg/mL soluble rabbit anti-human IgM, or BCGF + anti-IgM. Triplicate cultures of 1×10^5 cells per well were incubated in a final 0.2-mL-vol. ■, BCGF; ○, BCGF + anti-μ; ♦, anti-μ; ●, control.

incorporated in up to three days of culture. At day 6, proliferation was readily detected in BCGF-stimulated cultures, with ^{3}H-TdR incorporation increasing from day 6 to day 10, the last measurement. A combination of BCGF and anti-μ or anti-γ stimulation was also effective in initiating DNA synthesis, with increased activity of the combined stimuli on day 10. No proliferation was observed unless BCGF was present. The effect of anti–heavy-chain antibodies on different patients varied. Although no patient's cells showed spontaneous proliferation in the absence of BCGF and seven of eight responded to addition of BCGF with proliferation of > 1,000 cpm/10^5 cells, most patient samples demonstrated a significantly augmented response when anti–heavy-chain antibodies were added to cultures along with BCGF, and some showed similar levels of BCGF-stimulated DNA synthesis with or without anti–heavy-chain antibodies (Fig 2). In one patient who responded to BCGF with < 1,000 cpm (patient 4, Table 1), significant proliferation was achieved when insoluble anti-μ was added. In addition, in two patients for whom soluble anti-μ was compared to insoluble anti-μ, the insoluble form gave greater stimulation of DNA synthesis than did the soluble form. Overall, of seven patients tested with insoluble anti–heavy-chain antibodies, proliferation in five of the seven was significantly greater in the presence of the anti–heavy-chain antibodies. The remaining two patients showed only marginal augmentation in the presence of anti–heavy-chain antibodies.

Figure 3 shows the differential effect of α_2-IFN and γ-IFN on thymidine uptake. Neither recombinant α_2-IFN nor γ-IFN directly induced proliferative activity by HCL cells. However, the results indicate that 1,000 U/mL of α_2-IFN was capable of inhibiting BCGF-induced proliferation by cultured malignant HCL B cells. In contrast, 1,000 U/mL of recombinant γ-IFN did not have an antiproliferative effect when added to HCL cells in the presence of BCGF. As seen in Table 1, six of six patients tested for inhibition of proliferation by different IFN species were severely reduced in their ability to synthesize DNA in response to BCGF when cultured in the presence of 1,000 U/mL of α_2-IFN. Thymidine incorporation in the presence of both BCGF and α_2-IFN ranged between 6% and 35% of values obtained with BCGF alone, with a mean value of 17.5%. By the Wilcoxon test, the reduction in thymidine incorporation was significant with $P = .028$ when comparing BCGF alone with BCGF plus α_2-IFN. In contrast, γ-IFN was substantially inhibitory in only one case, patient 4. In the remaining five patients, γ-IFN enhanced proliferation in four and minimally reduced proliferation in one. The percentage of BCGF control ranged from a low of 21% in patient 4 to 70% to 190% in the remaining patients, with a

HCL, hairy cell leukemia; BCGF, B cell growth factor; IFN, interferon

For seven days, 1 × 10^5 cells per well were incubated with medium, 10% BCGF, 1,000 U/mL α_2-IFN or γ-IFN, and combinations of the above

*Because this patient did not proliferate to BCGF alone, the starred values give cpm when anti-μ was included with BCGF, and percentage of BCGF control is based on these values

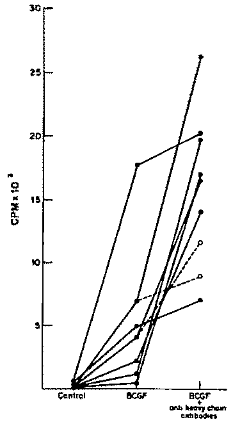

Fig 2. Effect of anti-μ or anti-γ on B cell growth factor (BCGF)-induced hairy cell proliferation. Cells from seven different hairy cell leukemia (HCL) patients were incubated in medium alone, with 10% BCGF, or 10% BCGF + 15 μg/mL soluble or insoluble anti-immunoglobulin heavy-chain antibodies for seven days. Thymidine was added for an additional 24 hours prior to harvesting. ●–●, insoluble; ○——○, soluble.

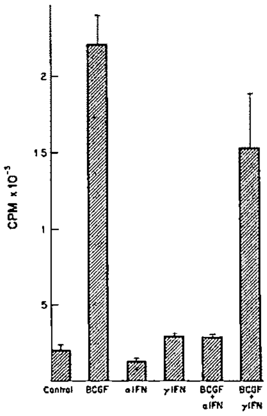

Fig 3. Effect of α_2-interferon (IFN) and γ-IFN on ^{3}H-thymidine incorporation. 1 × 10^5 hairy cell leukemia (HCL)-B cells per well (in triplicate) were incubated for seven days with medium alone, 10% B cell growth factor (BCGF), 1,000 U/mL of recombinant α_2-IFN, 1,000 U/mL of recombinant γ-IFN, or BCGF in combination with α-IFN or γ-IFN (cpm values represent the mean ± SE).

mean value of 114% ($P = .60$). It is clear that α_2-IFN and γ-IFN have differential effects on BCGF-induced proliferation of malignant hairy cells.

Effect of IFN on normal peripheral blood B cell proliferation. The normal B cell response to BCGF and anti-μ was qualitatively similar to the proliferation seen with hairy cells (Table 2). As with hairy cells, addition of 1,000 U/mL of recombinant α_2-IFN had an antiproliferative effect on BCGF/anti-μ–stimulated B cells. In addition, normal B cell proliferation was inhibited to some extent by γ-IFN, although α_2-IFN reduced proliferation to a greater degree than did γ-IFN (65% inhibition with α_2-IFN as compared with 20% to 39% inhibition by γ-IFN).

Lack of IL-2 activity in BCGF preparations. BCGF, supplied by Cellular Products, was confirmed to be free of IL-2 activity by both a ^{3}H-thymidine incorporation assay (Fig 4) and by a five-day growth assay (Table 3). A TCGF standard stimulated proliferation of T cell blasts in both thymidine incorporation and growth assays, whereas BCGF had no stimulatory activity in either assay.

Specific binding of ^{125}I-α_2-IFN by HCL cells. The binding curve shown in Fig 3 was generated by incubating HCL cells with ^{125}I-α_2-IFN in concentrations ranging from 0.5 to 50.0 ng per 10^7 cells, with or without a 40-fold excess of unlabeled α_2-IFN. Binding of ^{125}I-α_2-IFN increased up to the highest concentration tested and was inhibited by unlabeled recombinant α_2-IFN with a specificity of 69% to 86%. Saturation of binding sites was approached with increasing doses of ^{125}I-α_2-IFN (Fig 5). Scatchard analysis[21] (Fig 5, inset) revealed the apparent dissociation constant (Kd) to be 7.1×10^{-10} mol/L, indicating a high-affinity binding site. The approximate number of IFN receptors per cell (also based on Scatchard analysis) was calculated to be ~350.

A competitive inhibition experiment demonstrated that unlabeled recombinant α_2-IFN or β-IFN but not γ-IFN can effectively compete with ^{125}I-α_2-IFN for binding sites on HCL cells. α_2-IFN inhibited binding by 75.4%, β-IFN inhibited it by 67.9%, and γ-IFN showed no inhibition. This strongly supports the concept that α_2-IFN and β-IFN share a common receptor on malignant HCL cells and that the γ-IFN receptor, if present, is distinct, in agreement with the findings of Branca and Baglioni of unique receptors for types I and II IFNs on lymphoblastoid cell lines.[14]

Table 2. Seven-Day Thymidine Incorporation of Normal B Cells

Factor Added	Exp 1 (cpm)	Exp 2 (cpm)
Control	1,223	6,605
BCGF	14,161	16,955
Anti-μ	283	1,275
BCGF + anti-μ	11,543	13,079
BCGF, anti-μ, α-IFN	4,059	4,648
BCGF, anti-μ, γ-IFN	7,016	10,496
α-IFN	256	2,781
γ-IFN	259	2,997

Normal peripheral blood B cells were cultured for seven days at 1×10^6 cells per well (in triplicate) with RPMI 1640 and 20% FCS. Additions were as indicated: BCGF 10%, anti-μ 15 μg/mL (Bio-Rad 170-5120), α_2-IFN 1,000 U/mL, and γ-IFN 1,000 U/mL

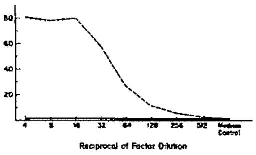

Fig 4. B cell growth factor (BCGF) was compared to a TCGF standard in assessing the presence of interleukin 2 in factor preparations. Phytohemagglutinin-activated T cells were added to dilutions of BCGF or TCGF at 1×10^5 per well, cultured for 48 hours at 37 °C, and then pulsed for 24 hours with ^{3}H-thymidine and harvested. ———, TCGF; ——, BCGF.

DISCUSSION

In our experience, BCGF has proven to be useful in stimulating HCL cells to divide in vitro. This is an important finding because standard B cell mitogens are relatively ineffective in inducing HCL proliferation. To date, no consistent or diagnostic chromosomal abnormality has been found in HCL, possibly due to the difficulty encountered in obtaining analyzable metaphases. BCGF may prove useful in extending cytogenetic or molecular genetic studies of HCL by stimulating cell division to a more easily quantitated level.

The effect of anti-heavy chain antibodies on BCGF-induced hairy cell proliferation was variable but, in most patients, it augmented BCGF-associated proliferation. However, anti–heavy-chain antibodies were not an absolute requirement for proliferation, as BCGF alone gave significant amounts of thymidine incorporation in the absence of anti-μ or anti-γ in most patients. Two subsets of B cells have been described by Muraguchi et al[7]: (a) a small, resting population of B cells that requires an activation step prior to becoming BCGF responsive; and (b) a larger, activated population that can respond directly to BCGF in the absence of prestimulation. This second subset may have been activated in vivo. It seems likely that some proportion of hairy cells fall into the second category, as they are large B cells that are capable of direct response to BCGF in the absence of activation by anti–heavy-chain antibodies.

BCGF may also prove useful in in vitro drug sensitivity testing on hairy cells and possibly other B-derived lympho-

Table 3. Lack of IL-2 Activity in BCGF Preparation

Factor Concentration (%)	Five-Day Cell Count ($\times 10^5$/mL)	
	TCGF	BCGF
20.00	22.6	0.4
10.00	22.7	0.7
5.00	18.3	0.2
2.50	6.1	0.4
1.25	4.2	0.4
0	0.5	0.5

Seven-day T cell blasts were prepared as described and added to 24-well plates at a starting concentration of 2×10^5/mL with varying concentrations of a T cell growth factor (TCGF) standard or with B cell growth factor (BCGF) to determine that no interleukin 2 activity was present in BCGF Plates were incubated for five days, and cell counts were determined by trypan blue exclusion.

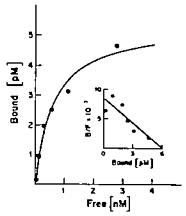

Fig 5. Specific binding of $^{125}I-\alpha_2$ interferon (IFN) to hairy cell leukemia cells. Lymphocytes (10^7) were incubated at 37 °C for one hour with 0.5 to 50 ng $^{125}I-\alpha_2$-IFN. Values shown are corrected for nonspecific binding, as assessed by inclusion of a 40-fold excess of unlabeled α_2-IFN. The Scatchard plot (inset) was generated by linear regression.

proliferative malignancies. To test antiproliferative capacity of a cell cycle-specific drug on tumor cells, measurable proliferation must be obtained prior to drug addition. In our studies with BCGF in combination with α_2-IFN and γ-IFN, α_2-IFN appears to inhibit DNA synthesis by the dividing hairy cells directly, whereas γ-IFN had no inhibitory effect in most patients tested and may even increase proliferation in some patients. The differential effects of types I (α and β) and II (γ) IFNs may be related to the fact that type I and II receptors are distinct, each IFN binding specifically to its own receptor.[14] It is likely that the biological effects and possible that the therapeutic effects of type I and II IFNs are also distinct. These observations may prove useful in determining the efficacy of different types of IFNs for therapeutic use, and the in vitro data predict that γ-IFN may have limited efficacy in this malignancy.

It is interesting to speculate on the mechanism of action of α_2-IFN in its successful treatment of hairy cell leukemia as compared with the less dramatic responses seen with other B cell tumors.[22] We have found α_2-IFN receptors on other types of malignant B cells from patients whose disease is relatively unresponsive to IFN therapy (data not shown), indicating that simple presence of receptors does not confer sensitivity to the therapeutic effects of IFN. As suggested by Hannigan et al,[13] resistance may be due to the lack of growth inhibitory effects of IFN on IFN-resistant cells, rather than to the absolute presence or absence of receptors. The fact that α_2-IFN directly inhibits hairy cell proliferation and γ-IFN does not suggests the possibility that α_2-IFN is exerting its therapeutic effects at least partially by direct inhibition of malignant cell growth rather than indirectly as a biological response modifier of non malignant cells.

Unlabeled α_2-IFN and β-IFN were each able to inhibit binding of $^{125}I-\alpha_2$-IFN to hairy cells, whereas γ-IFN was not capable of competing for the α_2-IFN binding site, indicating the presence of unique receptors for type I interferon on malignant B cells, as found on B cell lines.[14] These data indicate that IFN's therapeutic effects may be mediated by receptor-dependent phenomena in HCL. It may be possible to gain a clearer understanding of this interaction and its significance by attempting to modulate receptor expression in vitro by treatment with IFN and other lymphokines or by monitoring receptor expression in patients before and during IFN therapy.

ACKNOWLEDGMENT

We thank Dr Timothy Wozniak of the Wilmington Medical Center, Wilmington, Del, for patient samples invaluable to these studies, and Ms Gail Walsh for her assistance in preparing the manuscript. We also thank Dr Sally Schneider of the Department of Genetics and Endocrinology, RPMI, for assistance in data analysis, Dr Judy O'Malley of the Department of Biological Resources for antiviral titration of IFN preparations, and Dr Lawrence Emrich of the Department of Biomathematics for statistical analysis We thank Dr Richard Montagna of Cellular Products, Inc, for providing materials and advice for the TCGF assay

Impaired Expression of Cell Surface Receptors for B Cell Growth Factor by Chronic Lymphocytic Leukemia B Cells

By Robert T. Perri

Normal human B cell proliferation is controlled by various immunoregulatory signals including the T cell-derived lymphokine B cell growth factor (BCGF). The role of BCGF in the regulation of malignant B cell proliferation is unclear. Therefore, we studied the proliferative response of purified chronic lymphocytic leukemia (CLL) B cells to BCGF. For all CLL patients studied, CLL B cells showed a decreased proliferative response as compared with control B cells for BCGF-induced B cell proliferation (patient 291 ± 59 cpm *v* control 3,942 ± 622, mean ± SEM). This impaired proliferative response appeared to be intrinsic to CLL B cells since it was not corrected by incubation with increasing concentrations of BCGF. Attainment of normal B cell responsiveness to BCGF requires the processing of an initial activation signal which results in the expression of cell surface receptors for BCGF. Increasing concentrations of the B cell activation signal (the $F(ab')_2$ fragment of goat anti-human μ chain) did not improve CLL B cell responsiveness to BCGF. Three-day activated CLL B cells compared with activated control B cells demonstrated a marked impairment in their ability to absorb out the BCGF activity present in the BCGF preparation (BCGF activity absorbed out, patient 12.8% *v* control 53%). Pretreatment of CLL B cells with neuraminidase failed to improve either the proliferative response to BCGF or the expression of cell surface receptors for BCGF by the CLL B cells. This study suggests that the impaired responsiveness to BCGF by CLL B cells is the result of impaired expression of cell surface receptors for BCGF when CLL B cells are exposed to activation signals.

© 1986 by Grune & Stratton, Inc.

MOST CASES of chronic lymphocytic leukemia (CLL) represent a monoclonal expansion of B cells.[1] Most CLL B cells are not actively dividing and appear to be resting in the Go phase of the cell cycle.[2] Previous studies have demonstrated that CLL lymphocytes have an impaired response to the mitogenic signals of the plant lectins concanavalin A (Con A), phytohemagglutinin (PHA), and pokeweed mitogen (PWM).[3–5]

Normal human B cell proliferation is controlled by various immunoregulatory signals, including the T cell-derived lymphokine B cell growth factor (BCGF)[6–8] The stimulation of resting B cells to proliferate requires two signals.[9–12] The first signal required by the resting B cell is considered an activation signal. This activation signal results in the expression of cell surface receptors for BCGF. The expression of BCGF receptors provides the B cell with the capacity to respond to the proliferation signal delivered by BCGF. Normal human B cells are driven from their resting state to a proliferative state by this two-signal process.[9–12]

The role of BCGF in the regulation of malignant B cell proliferation is unclear. Previous studies have described autostimulatory activity produced by Epstein-Barr virus (EBV)-positive B lymphoblast cell lines.[13–16] In Namalva, an EBV-positive human B cell lymphoma line, this autostimulatory activity appears to be provided by BCGF.[16] A recent report identified malignant B cells from a patient with poorly differentiated lymphocytic lymphoma that proliferated in response to anti-human IgM alone.[17] Proliferation of this patient's malignant B cells was not enhanced by the addition of BCGF.

In the present study, we examined further the role of BCGF in the regulation of malignant B cell proliferation by studying the responsiveness of CLL B cells to the proliferation signal delivered by BCGF.

MATERIALS AND METHODS

Patients. After informed consent was obtained, B-CLL patients and normal control donors matched as closely as possible for age and sex were studied. When studied, none of the patients were receiving chemotherapy. Some patients had received chemotherapy within the month prior to the study.

Cell separations. Peripheral blood mononuclear cells were isolated from venous blood by Ficoll-Hypaque. Monocyte depletion was done by adherence in tissue culture flasks for 45 minutes at 37 °C in 5% CO_2. Non-adherent cells were harvested and were then allowed to rosette with AET-sensitized sheep erythrocytes (SRBCs) at 4 °C for two hours. Rosetted T cells were separated from the nonrosetted B cells by two successive Ficoll gradients. SRBCs were removed by hypotonic lysis with distilled H_2O. The twice nonrosetted B cell-enriched population (80% to 90% sIg+) was used in the following studies. T cell contamination in this population was <1% as determined by OKT3 reactivity. In addition, no mitogenic effect was noted when the B cell-enriched population was incubated with PHA (Difco Laboratories Inc, Detroit).

B Cell proliferation assay. This assay was performed as previously reported.[18] In brief, B cell proliferation was studied by culturing 5×10^4 control or CLL B cells obtained as described above in 0.2 mL of RPMI 1640 (GIBCO, Grand Island, NY) containing 10% heat-inactivated fetal calf serum (FCS) (Gibco) in 6-mm flat-bottomed microtiter wells (Linbro, Hamden, Conn). All experiments were done in triplicate. Plates were secured tightly and incubated at 37 °C with 5% CO_2 for three days. Various reagents were added to the cultures as indicated. In the standard proliferation assay, cells were cultured in the presence or absence of 10% BCGF (Celluluar Products, Buffalo) together with 1% (vol/vol) staphylococcal Protein A (SPA) (Sigma, St Louis) or goat $F(ab')_2$ anti-human IgM chain (Cappel, Cochranville, Pa) at 15 μg/mL. BCGF was prepared as previously described.[7] The purification scheme yielded a product free of immune interferon, interleukin 1 (IL-1)

and interleukin 2 (IL-2). This BCGF preparation supports both the short-term proliferation of activated human B cells[7,11,19] and the proliferation of human B cells in long-term culture.[11] This BCGF preparation does not support the proliferation of T cells.[11,19] It is primarily enriched for the human B cell stimulating factor (BSF) that appears to correspond to BSF-pl.[20] Both SPA 1% (vol/vol) and goat $F(ab')_2$ anti-human IgM chain 15 μg/mL gave comparable results when used as the initial activation signals in this B cell proliferation assay. The cultures were pulsed with ^3H-thymidine (1 μCi per well) (6.7 Ci/mmol/L, New England Nuclear, Boston) over the last 16 to 20 hours of incubation, harvested by a MASHII cell harvester in H_2O, and counted in a Packard scintillation spectrometer.

Absorption of BCGF activity by activated B cells Control or CLL B cells were prepared as described above. These control or CLL B cell-enriched populations were cultured for three days in the presence of SPA 1% (vol/vol) or varying concentrations of goat $F(ab')_2$ anti-human IgM chain. After this three-day incubation, 1 × 10^6 mL of viable control or CLL B cells were incubated for two hours at 4 °C in an equal volume mix with the BCGF preparation After this incubation, the preparation was tested for residual BCGF activity in the standard BCGF proliferation assay with freshly isolated control B cells as the target cells. Both SPA 1% (vol/vol) and goat $F(ab')_2$ anti-human IgM chain 15 μg/mL gave comparable results when used as the initial activation signals. Preabsorption values are those seen with the BCGF preparation before exposure to the three-day activated control or CLL B cells. Postabsorption values are those seen after exposure to the activated control or CLL B cells. PHA-stimulated lymphoblasts failed to absorb BCGF activity for the BCGF preparation. Percentage of activity adsorbed is calculated by dividing postabsorption cpm by preabsorption cpm then subtracting this from one, and multiplying that value by 100.

Neuraminidase treatment of B cells. Control or CLL B cells were isolated as described above As previously reported, 1 × 10^6 control or CLL B cells were incubated with neuraminidase (*Clostridium perfringens* 50 U/mL, Sigma) for 30 minutes at 37 °C with constant shaking.[21] The cells were then washed five to seven times and resuspended in RPMI 1640 with 10% FCS prior to their use in the proliferation assays described above.

RESULTS

The responsiveness of CLL B cells to the proliferation signal of BCGF was studied. The proliferative response of CLL B cells to BCGF was markedly impaired (Fig 1). In the presence of both an activation signal and BCGF, control B cells had a stimulation index of 16.7. In contrast, under similar culture conditions, CLL B cells had a stimulation index of only 2.3. All of the CLL B cells we have studied have demonstrated an impaired proliferative response to BCGF.

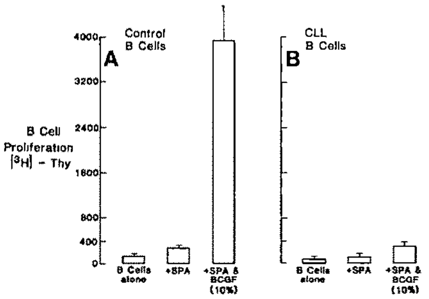

Fig 1. Comparison of (A) control and (B) CLL B cell proliferative responses to BCGF. Cultures were prepared as described in the Materials and Methods section. Data represent the mean ± SEM.

We next attempted to determine if CLL B cells were capable of responding to increased concentrations of BCGF (Fig 2). Control B cells responded to the proliferation signal of BCGF in a dose-dependent manner. In contrast, at all concentrations of BCGF studied, CLL B cells consistently exhibited a marked impairment in their proliferative response to BCGF.

We next sought to determine whether the impaired proliferative response of CLL B cells to BCGF was the result of impaired processing of the initial activation signal. Previous studies have demonstrated that the nature of the B cell activation signal provivded by anti-μ is dependent upon the concentration of anti-μ chosen.[11,12] Initially, we studied the effect of increasing concentrations of anti-μ on the responsiveness of CLL B cells to the proliferation signal of BCGF (Fig 3). As shown, increased concentrations of anti-μ as the initial activation signal did not improve the responsiveness of CLL B cells to the proliferation signal of BCGF.

Impaired processing of an initial activation signal by CLL B cells would be expected to result in decreased or abnormal expression of cell surface receptors for BCGF by the CLL B cells. Because these studies suggested that CLL B cells have an impaired activation response, we sought to determine if this impaired activation response by CLL B cells results in a defective expression of cell surface receptors for BCGF. In previous studies, the presence of receptors for BCGF on activated control B cells has been demonstrated by their ability to absorb out selectively the BCGF activity present in a BCGF preparation.[11] The ability of activated control and CLL B cells to absorb out the BCGF activity present in the BCGF preparation was studied (Table 1). As shown, activated control B cells were capable of absorbing out significant BCGF activity from the BCGF preparation. In contrast, activated CLL B cells demonstrated a marked impairment in their ability to absorb out BCGF activity from the BCGF preparation. These results suggest that CLL B cells have an impaired expression of cell surface receptors for BCGF. This impaired expression of BCGF receptors by CLL B cells may be the result of an impaired processing by CLL B cells of the initial activation signal.

A previous study demonstrated abnormal glycosylation of CLL T cell membrane components.[21] In an effort to determine if the impaired expression of BCGF receptors in response to activation signals by CLL B cells was the result

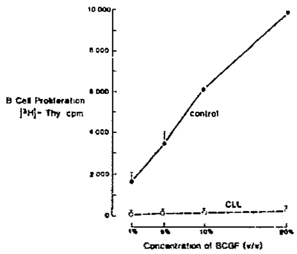

Fig 2. Proliferative response of control and CLL B cells to varying concentrations of BCGF in the presence of anti-μ (15 μg/mL). Cultures were prepared as described in the Materials and Methods section. Data represent the mean ± SEM.

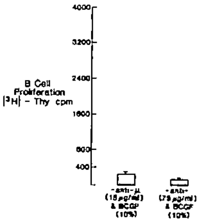

Fig 3. Proliferative response of CLL B cells to BCGF 10% (vol/vol) in the presence of varying concentrations of anti-μ. Cultures were prepared as described in the Materials and Methods section. Data represent the mean ± SEM.

of abnormal glycosylation of CLL B cell membrane components, we examined whether neuraminidase pretreatment of CLL B cells resulted in improved expression by CLL B cells of cell surface receptors for BCGF after an initial activation signal. CLL B cells were pretreated with neuraminidase before incubation with SPA 1% (vol/vol) for three days. The ability of neuraminidase-pretreated, three-day–activated CLL B cells to absorb out BCGF activity from the BCGF preparation was examined (Table 2). Neuraminidase pretreatment of CLL B cells did not result in enhanced expression of CLL B cell surface receptors for BCGF. Both neuraminidase-pretreated and nontreated CLL B cells had a similarly impaired capability to absorb out BCGF activity.

To confirm the failure of neuraminidase pretreatment to enhance CLL B cell BCGF receptor expression, we next studied the effect of neuraminidase pretreatment of CLL B cells on CLL B cell responsiveness to the proliferative signal of BCGF. No improvement in the proliferative response of CLL B cells to BCGF was seen when CLL B cells were pretreated with neuraminidase. Neither increased concentrations of neuraminidase nor longer preincubation times with neuraminidase resulted in any improvement in the proliferative response of CLL B cells to BCGF (data not shown). These results do not support the hypothesis that the impaired proliferative response of CLL B cells to BCGF is the result of abnormal glycosylation of CLL B cell membrane components.

Table 1. Defective Absorption of BCGF by CLL B Cells

BCGF (%) (vol/vol)†	Incorporation of ³H-Thymidine (cpm)* Preabsorption	 Postabsorption by Control B Cells	 Postabsorption by CLL B Cells	 Activity Absorbed (%)‡
10	5,351	2,438	—	54.4
20	7,727	3,633	—	53.0
10	5,351	—	4,495	16.0
20	7,727	—	6,734	12.8

BCGF, B cell growth factor, CLL, chronic lymphocytic leukemia.

*Incorporation of ³H-thymidine refers to the proliferative response of 5 × 10⁴ control B cells to staphylococcal Protein A (SPA) 1% (vol/vol) in the presence of the BCGF preparation, which was added both before and after absorption by SPA-stimulated control and CLL B cells. Cultures were incubated for three days with the addition of ³H-thymidine (1 μCi per well) for the last 16 hours. For the absorption of the BCGF preparation, control and CLL B cells were exposed to SPA 1% (vol/vol) for three days. After this interval, control and CLL B cells (10 × 10⁶ cells) were incubated for two hours at 4 °C with the BCGF preparation. After incubation, the preparation was tested for residual BCGF activity. Preabsorption values are those seen with the BCGF preparation before exposure to the SPA-activated B cells. Postabsorption refers to those values seen after exposure to the activated B cells Activated PHA-stimulated T lymphoblasts failed to absorb the BCGF activity.

†BCGF (vol/vol) refers to the final concentration of the BCGF preparation added to the proliferation assay.

‡Percentage of activity absorbed is calculated by dividing postabsorption cpm by preabsorption cpm, then substracting this from one, and multiplying that value by 100.

Table 2. Effect of Neuraminidase Treatment of CLL B Cells on Absorption of BCGF by CLL B Cells

BCGF (%) (vol/vol)†	Incorporation of ³H-Thymidine (cpm)* Preabsorption	 Postabsorption by CLL B Cells	 Postabsorption by Treated CLL B Cells	 Activity Absorbed (%)‡
10	9,495	7,042	—	25.8
20	13,611	11,110	—	18.4
10	9,495	—	7,469	21.3
20	13,611	—	13,183	3.2

BCGF, B cell growth factor; CLL, chronic lymphocytic leukemia.

*Incorporation of ³H-thymidine refers to the proliferative response of 5 × 10⁴ control B cells to staphylococcal Protein A (SPA) 1% (vol/vol) in the presence of the BCGF preparation, which was added both before and after absorption by SPA-stimulated neuraminidase-pretreated and nontreated CLL B cells. Cultures were incubated for three days with the addition of ³H-thymidine (1 μCi per well) for the last 16 hours. For the absorption of the BCGF preparation, CLL B cells were exposed to SPA 1% (vol/vol) for three days. Neuraminidase-treated and nontreated CLL B cells (10 × 10⁶ viable CLL B cells) were incubated then for two hours at 4 °C with the BCGF preparation. After incubation, the preparation was tested for residual BCGF activity. Preabsorption values are those seen with the BCGF preparation before exposure to the SPA-activated cells Postabsorption refers to those values seen after exposure to the activated cells. Activated PHA-stimulated T lymphoblasts failed to absorb the BCGF activity. Neuraminidase treatment of control B cells did not alter their absorption of BCGF.

†BCGF (vol/vol) refers to the final concentration of the BCGF preparation added to the proliferation assay.

‡Percentage of activity absorbed is calculated by dividing postabsorption cpm by preabsorption cpm, then substracting this from one, and multiplying that value by 100.

DISCUSSION

In this study, we have demonstrated that the malignant B cells in B-CLL have a markedly impaired response to the proliferation signal delivered by BCGF. The abnormal proliferative response to BCGF by CLL B cells appears to result from an impaired processing of the initial activation signals. Impaired processing of activation signals by the CLL B cells results in defective expression of cell surface receptors for BCGF by the CLL B cells. Alterations in the intensity of the initial activation signals did not improve the proliferative response to BCGF by CLL B cells. The impaired proliferative response of CLL B cells to BCGF does not appear to be the result of abnormal glycosylation of cell membrane components since neuraminidase pretreatment of CLL B cells did not improve either the proliferative response to BCGF or the expression of cell surface receptors for BCGF by CLL B cells.

Previous studies have identified intrinsic B cell defects in

CLL B cells. CLL B cells have a markedly impaired proliferative response to mitogenic signals such as PWM.[3-5] The addition of control T cells or monocytes did not improve the proliferative response of CLL B cells to PWM.[5] Decreased CLL B cell colony growth in in vitro B cell clonogenic assays has been reported.[22,23] Membrane abnormalities of CLL B cells have also been reported. CLL B cells incubated with anti-immunoglobulin reagents have abnormal dynamics of surface membrane immunoglobulin redistribution (capping).[24,25] In addition, impaired motility of CLL B cells has been described.[26,27]

The current model of normal B cell proliferation proposes that normal human B cell responsiveness to the proliferation signal of BCGF requires the expression of cell surface receptors for BCGF.[9-12] The processing of an initial activation signal by normal human B cells results in the expression of cell surface receptors for BCGF.[9-12] The presence on activated lymphocytes of receptors for specific growth factors (ie, IL-2 or BCGF) has been identified by their ability to absorb out selectively the specific growth factor activity from preparations containing the specific growth factor.[11] Other investigators have used a BCGF preparation similar to the preparation used in this study and have demonstrated that three-day, anti-μ–activated control human B cells can absorb out 55% of BCGF activity from this BCGF preparation.[11] In the current study, three-day SPA-activated control B cells absorbed out a nearly identical 54.4% of BCGF activity from the BCGF preparation. In contrast, CLL B cells consistently demonstrated a markedly impaired ability to absorb out BCGF activity from the BCGF preparation. These results suggest that CLL B cells have a defective expression of cell surface receptors for BCGF.

Cryptic or hidden expression of cell surface antigenic determinants by CLL T cells have been reported.[21] Some CLL T cells are E rosette positive but fail to react with OKT3, a monoclonal antibody specific for mature human T cells.[21] A cryptic or hidden antigenic expression of OKT3 by these CLL T cells was suggested by the finding that after neuraminidase treatment these CLL E rosette-positive, OKT3-negative T cells became reactive with OKT3.[21] The cryptic or hidden antigenic expression of the T3 antigen in these CLL T cells appears to be related to an as-yet-undefined membrane abnormality of CLL T cells that results from abnormal glycosylation of cell membrane components. The absence of any improvement in either CLL B cell proliferative response to BCGF or the expression of CLL B cell surface receptors for BCGF suggests that the abnormalities of CLL B cells reported in this study are not the result of cryptic BCGF receptor expression secondary to abnormal glycosylation of cell membrane components.

Other studies have suggested that CLL B cell dysfunction is a result of impaired differentiation.[28-31] The expression of surface membrane immunoglobulin by CLL B cells is markedly less than that expressed by more differentiated B cells.[1] It has been suggested that only normal B cells that express surface IgG are responsive to PWM.[32] Because most CLL B cell surface immunoglobulin is IgM, it has been theorized that CLL B cells may fail to respond to PWM because they lack the binding sites for PWM [5]

Murine studies have suggested that the influence of proliferation signals such as BCGF on B cells is affected by the stage of development of the target B cell.[33,34] Anti-immunoglobulin stimulation of BCL1 murine malignant B cells did not result in increased proliferation unless the BCL1 B cells had assumed a more mature phenotype before exposure to the anti-immunoglobulin.[33] Anti-immunoglobulin stimulation could not induce proliferation of normal immature murine B cells.[33]

The stage of human B cell development and differentiation during which normal B cells are responsive to BCGF is not yet known. A recent study has demonstrated that B cells responsive to BCGF may be selected by the presence on the B cell of the B2 surface antigen [35] B2 is a 140-kd glycoprotein[36] that expresses distinct binding sites for C3d[37] and for EBV.[38] B2 first appears on the cell surface after the cytoplasmic μ-chain–positive pre-B cell stage[39] and is lost when surface IgD is no longer detectable.[40] B2-positive B cells were responsive to the proliferation signals of anti-μ and anti-μ plus PHA-stimulated leukocyte-conditioned media (PHA-LCM).[35] If CLL is a disorder characterized by a clonal expansion of immature B cells,[28-31] such immature B cells may not have developed a responsiveness to the proliferation signal of BCGF.

A recent study has demonstrated some proliferative responsiveness of CLL B cells to "T cell factors."[41] However, induction of CLL B cell proliferation required activation by anti-immunoglobulin at 200 μg/mL. In that study, data on the effectiveness of more conventional concentations of anti-immunoglobulin as an initial activation signal were not presented. However, even with a 15-fold increase in the concentration of anti-μ, the stimulation index was only 3.8, comparable to results in this study in which the stimulation index was 3.1 when anti-μ at 15 μg/mL was used as an activation signal. That occasional CLL B cells may be capable of some degree of responsiveness to BCGF is suggested by the reported ability of BCGF to support the growth of some leukemic B cells in vitro for periods of up to 60 days.[11]

This study does not resolve the role of BCGF in regulating CLL B cell proliferation. It does show that the impaired responsiveness to BCGF by CLL B cells is the result of impaired expression of receptors for BCGF when CLL B cells are exposed to activation signals. The apparent arrest of CLL B cells at an immature stage of B cell development may have impact upon the responsiveness of the malignant B cell to the proliferation signal of BCGF. Because some CLL B cells may be induced to further differentiation by agents such as phorbol esters,[29-31] we have begun to investigate whether in vitro-induced differentiation of CLL B cells results in improved CLL B cell responsiveness to BCGF. Impaired responsiveness to immunoregulatory lymphokines such as BCGF may contribute to the significant hypogammaglobulinemia observed in CLL patients.

ACKNOWLEDGMENT

I would especially like to thank Kristen Powell for her excellent technical assistance throughout this study.

Leukopenic Chronic T Cell Leukemia Mimicking Hairy Cell Leukemia: Association With Human Retroviruses

By C.C. Sohn, D.W. Blayney, J.L. Misset, G. Mathé, G. Flandrin, E.M. Moran, F.C. Jensen, C.D. Winberg, and H. Rappaport

We report two cases of a T cell lymphoproliferative disease not previously described, with cytologic and clinical features similar to those associated with Galton's "prolymphocytic" leukemia (PL). Our patients, like those with Galton's PL, had massive splenomegaly and minimal or absent hepatomegaly and lymphadenopathy. In contrast, however, our patients had leukopenia, as well as low percentages of leukemic cells in the peripheral blood and in the bone marrow. In splenic imprints, the nuclear chromatin pattern of most of the leukemic cells was intermediate between those of mature lymphocytes and those of lymphoblasts, and the nuclei contained single, centrally located, conspicuous nucleoli. In sections of the spleen, the leukemic cells diffusely infiltrated the red pulp in a pattern strikingly similar to that of hairy cell leukemia; however, when the leukemic cells were studied cytochemically, the cytoplasmic acid phosphatase positivity was punctate and tartrate-sensitive. The leukemic cells were sheep erythrocyte rosette-positive and expressed T cell-associated antigens. Initially, both patients responded well to therapeutic splenectomy. One patient received combination chemotherapy after splenectomy and is alive and well 24 months after diagnosis. The other patient was in complete clinical remission for one year after splenectomy and received chemotherapy at relapse. He died, however, 23 months after splenectomy, with disseminated disease. IgG antibody titers against human T lymphotropic virus type I (HTLV-I) were detected in one patient and against HTLV-II in the other. The leukemia in these patients represents a distinct clinicopathologic entity within the spectrum of peripheral T cell lymphoproliferative diseases that includes Galton's PL of T cell derivation, T cell chronic lymphocytic leukemia, T cell hairy cell leukemia, and adult T cell leukemia/lymphoma.

© 1986 by Grune & Stratton, Inc.

THE CLINICOPATHOLOGIC and immunophenotypic heterogeneity of T cell malignancies is reflected in the growing list of T cell lymphoproliferative diseases that includes chronic lymphocytic leukemia (CLL),[1-6] hairy cell leukemia (HCL),[7-10] adult T cell leukemia/lymphoma (ATL), and peripheral T cell lymphoma,[11-18] as well as mycosis fungoides/Sézary syndrome,[19-22] and acute lymphoblastic leukemia/lymphoma.[3,23-25] Even within T cell CLL (T-CLL), several immunophenotypic and/or morphologic subtypes have been recognized,[4,5] one of which is the so-called T cell "prolymphocytic" leukemia* (PL).[5]

Galton et al[26] initially described PL as a distinct clinicopathologic variant of CLL characterized by marked lymphocytosis, massive splenomegaly, lesser hepatomegaly, and minimal or absent lymphadenopathy. Although most PLs have been shown to be of B cell derivation,[26,30-37] T-PLs[1,5,11,30,34,35,38-44] and PLs with co-expression of T and B cell markers[45] have also been described. Regardless of the immunophenotype, most reported cases of PL have conformed remarkably well to Galton's clinicopathologic criteria.

We recently encountered two cases of a leukopenic T cell leukemia in which there was massive splenomegaly but mild hepatomegaly and minimal lymphadenopathy, similar to the findings in Galton's PL and in HCL. The splenomegaly resulted from diffuse infiltration of the red pulp by lymphocytes morphologically resembling those of Galton's prolymphocytes. The presence of leukopenia distinguishes our cases from cases of Galton's PL, however, and the morphology and cytochemistry of the leukemic cells distinguish our cases from those of T-HCL. We evaluated the morphologic, immunologic, hematologic, clinical, and serologic findings in these two cases in an effort to further define the spectrum of T cell lymphoproliferative diseases.

MATERIAL AND METHODS

The presplenectomy and postsplenectomy morphological, immunologic, hematologic, and clinical material from case 1 originated from the Service des Maladies Sanguines et Tumorales (ICIG), Hôpital Universitaire Paul-Brousse, Villejuif, France. The material from case 2 was contributed by the Hematology-Oncology Section of the VA Medical Center, Long Beach, Calif, to the James Irvine Center for the Study of Leukemia and Lymphoma at the City of

---

*"Prolymphocytic" leukemia as described by Galton et al[26] is a rare variant of CLL and differs from the prolymphocytic variant of acute lymphoblastic leukemia that has been described by one of us (G.M.).[27,28] We agree with Huhn[29] that the term prolymphocytic as applied to Galton's PL does not reflect our current knowledge about the stage of differentiation of the leukemic cells but, in accordance with the numerous existing reports on Galton's PL and for the sake of convenience, we will use the designation PL for the disease described by Galton.

Hope National Medical Center. Permission to use this material for research purposes, in addition to diagnostic evaluation, was granted by the Institutional Review Board of the City of Hope National Medical Center.

Morphologic Studies

Tissue for light microscopy was fixed in Bouin's solution in case 1 and in 10% buffered formalin in case 2, embedded in paraffin, and stained with hematoxylin and eosin. Touch imprints were available from the spleen in case 1 and from the spleen and splenic lymph nodes in case 2. The touch imprints as well as the blood and bone marrow smears were stained with May-Grünwald Giemsa.

Cytochemical Studies

Stains for acid phosphatase and for tartrate-resistant acid phosphatase were done on splenic imprints in case 1 and on blood smears in case 2. The α-naphthyl acetate esterase (ANAE) stain was done on blood smears in both cases. The cytochemical studies were carried out according to methods described previously.[46]

Immunologic Studies

The preparation of cell suspensions from solid tissues, the separation of mononuclear cells by Ficoll-Hypaque density gradient centrifugation, and the immunologic study of the cell suspension samples were carried out as previously described.[47,48] Neuraminidase-treated fresh sheep erythrocytes were used for the quantitation of spontaneous sheep erythrocyte rosette (sER) formation.

Cell suspensions were prepared from the spleen in case 1 and from the peripheral blood in case 2. In case 1, Leu-4 (Becton Dickinson, Sunnyvale, Calif) and T4 and T8 (Coulter Immunology, Hialeah, Fla) were used as T cell markers, and rhodamine-conjugated F(ab')2 fragments to human γ, α, μ, κ, and λ chains (Kallestad Laboratories, Austin, Tex) were used for the study of surface immunoglobulins. In case 2, T11 (Coulter Immunology) was the pan-T cell marker, and γ, α, μ, δ, κ, and λ immunoabsorbed F(ab')2 goat anti-human immunoglobulins labeled with fluorescein isothiocyanate (FITC) (Tago, Burlingame, Calif) were used for detection of surface immunoglobulins.[48] In case 2, the peripheral blood lymphoid cells were also studied by a reference laboratory (Specialty Laboratories, Inc, Los Angeles) which used OKT4 and OKT8 (Ortho Diagnostics, Raritan, NJ) as T cell markers according to standard procedures. Terminal deoxynucleotidyl transferase (TdT) activity was determined with an indirect immunofluorescence method as previously described.[47]

Serologic study for human T cell lymphotropic virus (HTLV)

Serum samples were collected, frozen, and later tested for antibodies to the HTLV by an enzyme-linked immunoabsorbent assay (ELISA) developed at Cytotech, Inc, San Diego, Calif.[49] HTLV-I was harvested from the supernatant of a cell line producing this variant (C10/MJ2, provided by Dr R. C. Gallo), HTLV-II was harvested from the 344 cell line (provided by Drs R. C. Gallo and M. Popovic), and HTLV-III was harvested from a HUT 78 cell line transfected with this virus (HUT 78/013LK). Virus-producing cells were pelleted by centrifugation, and extracellular virus was concentrated. After gradient fractionation, the purified virus was resuspended in phosphate-buffered saline (PBS) and pelleted.[49] Donor serum was diluted to 1:100 for assay. Goat anti-human IgG conjugated to glucose oxidase was used as a labeling antibody and was counterstained. The development of a green hue was determined at 405 nm in a Multiscan (Flow Laboratories, McLean, Va) automated spectrophotometer after exactly 30 minutes of incubation. Specimens were scored as positive if absorbance was 1.8 times that of a standard negative control sample for HTLV-II and 3.0 for HTLV-I and HTLV-III. Western blot analysis for HTLV-I and HTLV-III was performed as previously described.[50]

Case reports

Case 1. A 42-year-old white woman from Sicily was referred to the Hôpital Universitaire Paul-Brousse, Villejuif, France, with asthenia, low-grade fever, and a two-month history of a rapidly growing abdominal mass in the left upper quadrant. The spleen was palpable 10 cm below the left costal margin, and the liver was palpable 5 cm below the right costal margin. The patient had minimal cervical and inguinal lymphadenopathy. Peripheral blood studies revealed a WBC count of $1.9 \times 10^9/L$ with a differential count of 32% lymphocytes, 10% lymphoid cells with single conspicuous nucleoli (Fig 1a), 44% bands and neutrophils, 3% metamyelocytes, 2% eosinophils, and 9% monocytes. The Hb level was 7.2 g/dL, and the platelet count was $112 \times 10^9/L$. The bone marrow biopsy specimen was hypercellular and partially infiltrated by lymphoid cells. The bone marrow aspirate smear had originally been reported to contain 30% lymphoblasts. On review, most of these cells were interpreted as having the appearance of Galton's prolymphocytes. At splenectomy, the spleen was found to be grossly enlarged and involved by a leukemic process (Fig 2a) characterized, on touch imprints, by atypical lymphoid cells, the nuclei of which had single conspicuous nucleoli (Fig 2b). The liver biopsy specimen showed involvement by leukemia (Fig 3).

After splenectomy, the patient's WBC count slowly increased to $12 \times 10^9/L$, accompanied by an increase in the percentage of leukemic cells. There was also a transient increase in the percentage of normal-appearing monocytes. The postsplenectomy bone marrow specimen showed diffuse lymphoid leukemic infiltrations (Fig 4). The patient was treated with prednisone, vincristine, L-asparaginase, and doxorubicin, followed by maintenance therapy with 6-mercaptopurine, methotrexate, and vindesine, and by intensification therapy every three months. The agents used for intensification therapy were doxorubicin and vincristine, with either cyclophosphamide or cytosine arabinoside given alternately in successive intensification

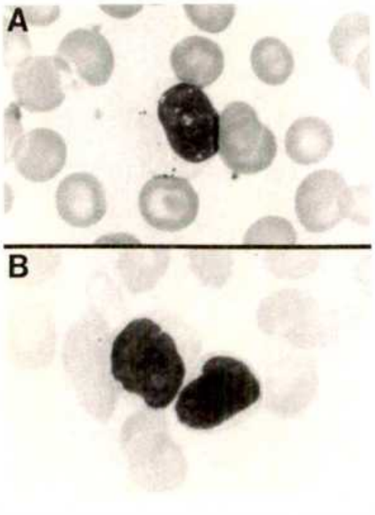

Fig 1. Peripheral blood. (A) Case 1, showing a lymphoid cell with relatively abundant cytoplasm that contains several azure granules. The ovoid nucleus has a distinct nucleolus and chromatin of intermediate coarseness. (B) Case 2. Two circulating atypical lymphoid cells show moderately abundant cytoplasm, deep nuclear indentation, and distinct nucleoli. May-Grünwald Giemsa. (Original magnification ×1360; current magnification ×816.)

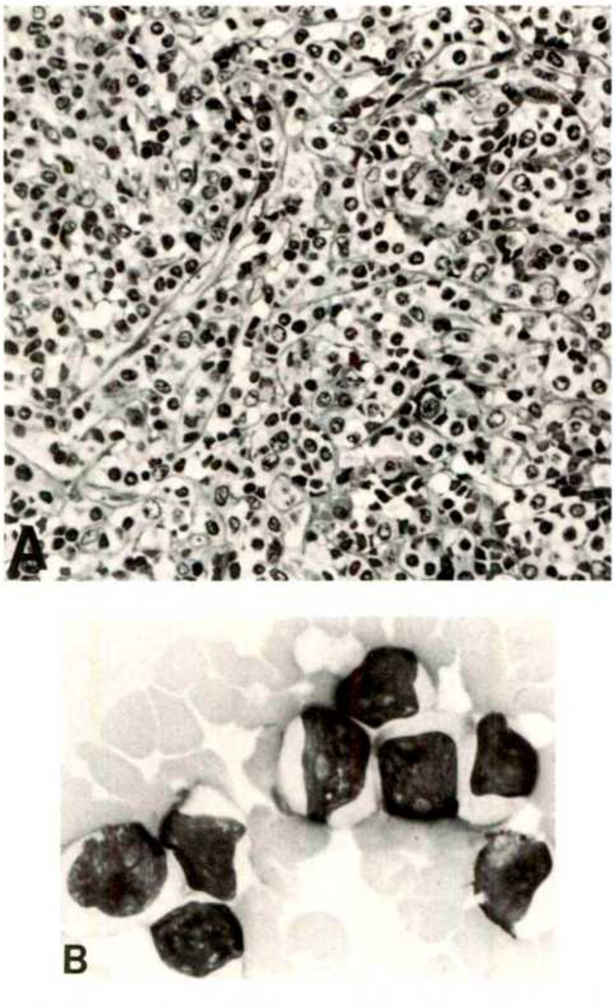

Fig 2. (A) Spleen, case 1. Red pulp showing diffuse invasion of cords and sinuses by the abnormal lymphoid cells. The abundant clear cytoplasm of many of the cells mimics the appearance of hairy cells. Hematoxylin and eosin stain: (magnification ×340.) (B) Splenic imprints exhibiting the characteristic features of the leukemic cells. The atypical lymphoid cells are characterized by a relatively abundant cytoplasm, irregular nuclear contours, distinct nucleoli, and, in most cells, a chromatin pattern intermediate between that of lymphoblasts and that of mature lymphocytes. May-Grünwald Giemsa stain. (Original magnification ×1360; current magnification ×884.)

courses. The patient has remained clinically well for 24 months, although a few leukemic cells have persisted in the peripheral blood.

Case 2. A 48-year-old black American man from Los Angeles had pancytopenia and splenomegaly at diagnosis. The spleen was palpable 10 cm below the left costal margin; there was no appreciable hepatomegaly or peripheral lymphadenopathy. The patient's peripheral blood showed a WBC count of $1.2 \times 10^9/L$, an Hb level of 9.2 g/dL, and a platelet count of $78 \times 10^9/L$. The WBC differential count showed 60% lymphocytes, including "abnormal lymphocytes" (Fig 1b), 16% neutrophils, 5% bands, 1% eosinophils, and 18% monocytes. The slightly hypercellular bone marrow biopsy specimen showed no detectable leukemic infiltration, but 8% of the cells in the bone marrow aspirate smear were lymphoid cells of intermediate size with single conspicuous nucleoli. At splenectomy, the spleen was found to be massively enlarged. Microscopic evaluation of spleen, splenic hilar lymph node, and liver biopsy specimens showed leukemic involvement. After splenectomy, the WBC count, Hb level, and platelet count returned to normal, although leukemic cells persisted in the peripheral blood. The patient was followed at monthly intervals and remained clinically well for one year.

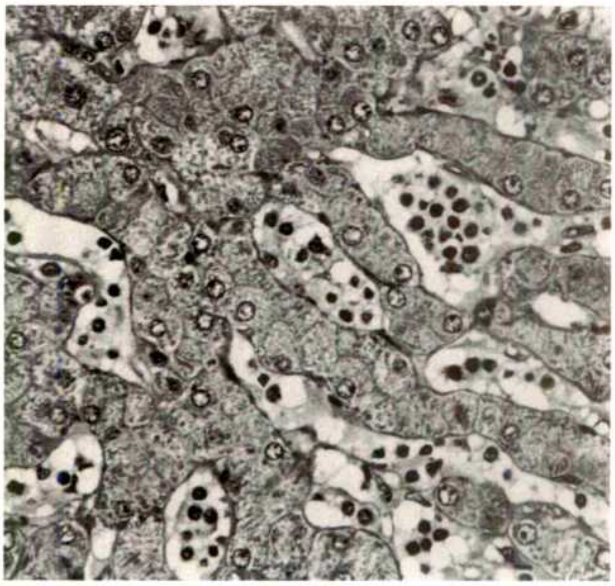

Fig 3. Liver biopsy, case 1, showing diffuse infiltration and distention of the liver sinusoids by abnormal lymphoid cells. This leukemic pattern closely resembles that observed in hairy cell leukemia. Hematoxylin and eosin. (Magnification ×340.)

Twelve months after splenectomy, the patient had a sudden, steady increase in the number of circulating leukemic cells. Biopsy specimens of bone marrow and axillary lymph nodes contained extensive leukemic infiltrates (Fig 5). Monthly five-day courses of

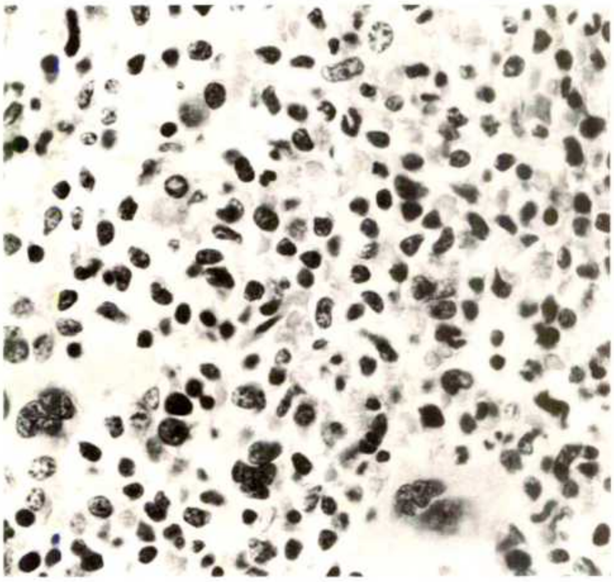

Fig 4. Bone marrow specimen, case 1 (postsplenectomy), with diffuse infiltration by lymphoid cells that exhibit variations in nuclear size and shape as well as irregularity of nuclear contours. Residual megakaryocytes are evident. Hematoxylin and eosin stain. (Magnification ×540.)

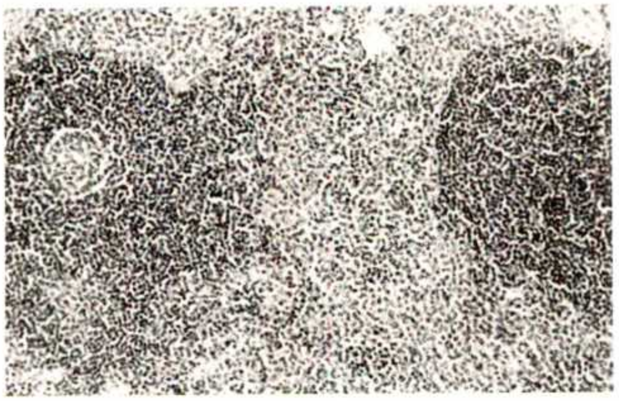

Fig 5. Lymph node, case 2, one year after splenectomy. A paracortical proliferation of abnormal lymphoid cells is in keeping with the T cell phenotype but also resembles the cellular distribution seen in lymph nodes involved by hairy cell leukemia. Hematoxylin and eosin stain. (Magnification ×110.)

chlorambucil and dexamethasone were begun when the WBC count reached $52.5 \times 10^9/L$, with almost exclusively leukemic cells; this therapy controlled but did not eradicate the leukemic cells in the peripheral blood. Five months later, the patient was again found to have an increase in the number of peripheral blood leukemic cells as well as hepatomegaly. The chemotherapy was changed to monthly cycles of cyclophosphamide, vincristine, procarbazine, and prednisone. Over the next three months, the patient's WBC count varied from 2.8 to $9.1 \times 10^9/L$, with 2% to 54% leukemic cells. The patient died of disseminated leukemia 23 months after clinical presentation. A postmortem examination was authorized and performed.

The clinical and antemortem pathologic findings in both cases are summarized in Table 1.

RESULTS

Morphologic Findings

Peripheral blood. The leukemic cells from both patients were atypical lymphocytes with relatively abundant cytoplasm. The nuclei had round to oval contours, often with one and sometimes two deep indentations. The chromatin pattern was of intermediate coarseness; usually, there was a single conspicuous nucleolus (Fig 1a and b). In case 1, the cytoplasm of many of the leukemic cells contained several azure granules (Fig 1a). No cytoplasmic granules were identified in the leukemic cells of case 2 (Fig 1b). After splenectomy, the presence of leukemic cells in the peripheral blood was more obvious because the number of circulating leukemic cells increased as the disease progressed.

Bone marrow. In case 1, the core biopsy specimen obtained prior to splenectomy showed hypercellular marrow, with persistent erythroid and megakaryocytic foci, partially infiltrated by mononuclear cells in a pattern resembling that of HCL.[51,52] The aspirate smear contained 30% atypical lymphoid cells with the same appearance as that of the leukemic cells in the peripheral blood. In case 2, there was no detectable leukemic infiltration in the initial core biopsy. The aspirate smear in this case showed only 8% leukemic cells.

In the postsplenectomy bone marrow biopsy specimens from both patients, more prominent, diffuse leukemic infiltration was evident. The lymphoid cells showed variations in nuclear size and shape and had irregular nuclear outlines (Fig 4).

Spleen. The spleens in cases 1 and 2 weighed 2,460 and 2,394 g, respectively. The cut surfaces were homogeneous and free of tumor nodules; Malpighian corpuscles were not grossly visible.

In microscopic sections, the leukemic cells filled the red-pulp cords and sinuses and encroached on or obliterated the white pulp; the pattern of involvement was strikingly similar to that in HCL (Fig 2a). The leukemic cells were of medium size and had round to oval nuclei. In routine histologic sections, the chromatin appeared less heavily clumped than in the lymphocytes of CLL. The nucleolus was often difficult to identify except when cells were examined under oil immersion. Irregularities in the nuclear contours, including deep indentations, were noted in a few of the cells. In touch imprints prepared from the spleens, the moderately coarse chromatin pattern, the single centrally located nucleolus, and the moderate to abundant pale-blue cytoplasm were clearly evident (Fig 2b).

Liver. Liver biopsy specimens from both patients contained mononuclear cell infiltrates in the sinusoids and portal areas. The pattern of infiltration, although nonspecific, resembled that of HCL (Fig 3). In the histologic sections, the cytologic features of the leukemic cells were not clearly apparent. The leukemia could not have been classified by the sections of the liver biopsies alone.

Lymph nodes. In case 2, splenic hilar lymph nodes obtained at the time of splenectomy contained leukemic infiltrates in the paracortical and medullary areas. Scattered atypical cells were identified in distended sinuses. The lymph nodes were initially interpreted as being reactive but, with the aid of the lymph node touch imprints which showed clusters of cells having single conspicuous nucleoli, they were reinterpreted as containing focal leukemic infiltrates. Focal plasma cell infiltration was also present. In the axillary lymph nodes in case 2, biopsied one year after splenectomy, sheets of leukemic cells expanded the paracortical areas and filled the sinuses (Fig 5).

Table 1. Clinical Findings

		Physical Findings at Diagnosis			Bone Marrow at Diagnosis		
					Leukemic Cells		
Cases	Age/Sex	Spleen (g)	Liver	Lymph Nodes	Biopsy	Smear	Follow-up (ms)
1	42 F	2,460	5 cm*	Minimal cervical and inguinal adenopathy	Partially infiltrated	30%	Clinically well (24)
2	48 M	2,394	Not enlarged	Not enlarged	Not detected	8%	Dead (23)

*Below right costal margin.

Postmortem examination. In Case 2, an autopsy was performed, revealing marked hepatomegaly (3,600 g) as well as moderate lymphadenopathy involving the mediastinum and the porta hepatis. Histologically, the liver contained extensive mononuclear cell infiltrates in the sinusoids and portal tracts. The lymph nodes and bone marrow were massively and diffusely involved by leukemia, whereas scattered leukemic cells were found within the interstitial tissues of the kidneys.

Immunologic and Cytochemical Findings

In case 1, immunologic studies of the cell suspensions prepared from the spleen indicated that the predominant lymphoid cell population expressed an immunophenotype consistent with that of suppressor T cells (Table 2). The majority of the cells were sER$^+$, Leu-4$^+$, T4$^-$, T8$^+$. Three percent of the cells were surface immunoglobulin (sIg) positive and had a polyclonal distribution. In case 2, the peripheral blood lymphoid cells studied at the time of lymphocytosis (one year after splenectomy) were sER$^+$, T11$^+$. They were TdT$^-$. Six percent were sIg$^+$; these cells also had a polyclonal distribution. The lymphoid cells in a presplenectomy peripheral blood specimen studied by a reference laboratory were reported as OKT4$^-$, OKT8$^-$.

In both cases, the acid phosphatase stain resulted in paranuclear granular cytoplasmic positivity which was tartrate-sensitive and often punctate in appearance. The ANAE stain also resulted in punctate, paranuclear cytoplasmic positivity, which was not diminished by sodium fluoride treatment.

Serologic Study for HTLV

Frozen serum from case 1 contained IgG antibodies to HTLV-I. The ratio of absorbance of patient serum to that of standard negative control serum was 8.4. Western blot analysis of this patient's serum was positive against HTLV-I target. Furthermore, the ratio of the HTLV-III target was 11.8, but no HTLV-III proteins were detected in the western blot system. The ELISA assay for HTLV-II was negative. Serum from case 2, obtained shortly before the patient's death, was positive for HTLV-II, with an absorbance ratio of 1.9. This specimen was negative in the ELISA assays for HTLV-I (ratio 0.9) and HTLV-III (ratio 0.96). The specimen from case 2 was also negative for HTLV-I and HTLV-III on western blot analysis.

DISCUSSION

Recent advances in immunologic techniques and the use of multidisciplinary approaches have greatly facilitated not only the identification of T cell lymphoproliferative disorders, but also the study of the state of differentiation of the neoplastic cells. Such studies have supported the assumption that chronic T cell leukemias, including Galton's PL, T cell type, are in fact derived from postthymic T cells.[3,10,43,44,53,54] Recent studies have also revealed a spectrum of clinicopathologic and immunophenotypic heterogeneity within chronic T cell leukemias, resulting in the identification of several subtypes.[1-6] We have described two cases of a chronic T cell leukemia which, we believe, represents a distinct leukopenic variant of Galton's PL.

The leukemia in the two cases reported here can be distinguished cytologically from CLL,[55] including classical T-CLL,[1] which may be associated with massive splenomegaly. This distinction can be made primarily on the basis of the chromatin pattern of the leukemic cells, which is of intermediate coarseness, and on the presence of a single conspicuous, usually centrally located nucleolus. We wish to emphasize the importance of touch imprints (Fig 2b) and of well-prepared peripheral blood and bone marrow aspirate smears for recognition of the distinctive cellular morphology of the leukemic cells. Architectural features are helpful in distinguishing leukopenic chronic T cell leukemia from lymphocytic lymphomas of intermediate or poor differentiation that present primarily in the spleen.[56] The latter display "miliary" or multifocal patterns of splenic involvement,[56] whereas in our cases the spleens were diffusely infiltrated. Likewise, the pattern of infiltration of the liver was characteristically a leukemic one (Fig 3), involving both sinusoids and portal triads without even minimal tumor formation.

The initial pancytopenia and the massive, diffuse involvement of the spleen in our two cases were findings reminiscent of those in HCL. Diffuse splenic involvement is known to occur in both B-PL and T-PL, however.[32,35] The cytologic features of the leukemic cells in our cases were those of Galton's prolymphocytes and not those of HCL; moreover, the leukemic cells exhibited punctate cytoplasmic acid phosphatase positivity that was tartrate-sensitive. Although single prominent nucleoli have been noted in the so-called "indented" type of HCL,[52] the leukemic cells in this type had notched or kidney-shaped nuclei, and their cytoplasm displayed tartrate-resistant acid phosphatase positivity. Pa-

Table 2. Hematologic, Cytochemical, and Immunologic Findings at Diagnosis

				Peripheral Blood			Immunologic Markers			ELISA HTLV			Western Blot HTLV	
Case	WBC (× 10^9/L)	Platelets (× 10^9/L)	Hemoglobin (g/dL)	(%) Lymphocytes	(%) Prolymphocytes	Cytochemistry AcP/TRAP	(%) sER	(%) (Antibody Used)	(%) sIg	I	II	III	I	III
1	1.9	112	7.2	32	10	+/−	65	92 (Leu4) 4 (T4) 80 (T8)	3	+	−	+	+	−

*An unspecified percentage of abnormal lymphocytes was noted in the initial peripheral blood smear, which was not available for review.

AcP, acid phosphatase; TRAP, tartrate-resistant AcP; +, positive; −, negative; sER, spontaneous rosettes with sheep erythrocytes; sIg, surface immunoglobulin; ELISA, enzyme-linked immunoabsorbent assay.

tients with this type of HCL generally did not have massive splenomegaly, but they tended to have marked bone marrow and lymph node involvement when first examined. The patients reported as having T-HCL or T- and B-HCL tended to have relatively slow clinical progressions.[7,8,10]

Only after splenectomy did our patients develop increases in the number of circulating leukemic cells and more extensive bone marrow involvement. At this stage of the disease, the morphologic and clinical findings were indistinguishable from those in Galton's PL. The patient who was treated with splenectomy and combination chemotherapy is clinically well 24 months after diagnosis, despite the persistence of a few circulating leukemic cells. The patient who was initially treated with splenectomy alone had a clinical remission for one year, but died nine months later with progressive disease. Treatment after relapse with chlorambucil and dexamethasone and then with cyclophosphamide, vincristine, procarbazine, and prednisone was not successful in controlling the disease.

No significant superficial lymph node enlargement was clinically evident at the outset. Minimal involvement of the splenic lymph nodes was noted in case 2 at the time of splenectomy. Enlarged axillary lymph nodes removed one year after splenectomy revealed incomplete involvement of the nodes, with a paracortical pattern of infiltration. This pattern was consistent with the T cell derivation of the neoplastic cells, but it may also be observed in HCL.

Our two cases expand the spectrum of lymphoproliferative diseases associated with various HTLV, which constitute a family of human RNA tumor viruses with T cell tropism.[57] HTLV-I, antibodies to which were found in our case 1, is associated with ATL,[58] usually involves phenotypic helper T cells, and is characterized clinically by skin lesions, lymphadenopathy, hepatosplenomegaly, hypercalcemia, and an aggressive clinical course.[11,59] In our case 1, however, the malignant cells expressed a T suppressor phenotype and clinically resembled an "aleukemic" form of lymphocytic leukemia rather than the ATL syndrome. The serologic cross-reactivity with HTLV-III seen in case 1 (i.e., ELISA positive, but negative in the western blot) is a recognized phenomenon.[60]

HTLV-II, antibodies to which were found in our case 2, is distinct from HTLV-I, based on serologic and molecular parameters, and has previously been reported in only one unusual case of T-HCL.[7,61] In contrast, our case 2, although resembling HCL with respect to its clinical presentation and to the patterns of distribution of the leukemic cells in the spleen, liver, and lymph nodes, was, in fact, a variant of chronic T cell lymphocytic leukemia in which the proliferating cells differed both morphologically and cytochemically from hairy cells.

That two clinically and pathologically similar cases were associated with antibodies against different variants of HTLV is of interest, although the significance is not clear, since the presence of these antibodies does not necessarily mean that HTLV is causally related to the evolution of the leukemia reported in our two patients. The presence of these antibodies may merely indicate coincidental infection or immunologic cross-reactivity with a previously unrecognized member of the HTLV group of viruses. Tissues involved by the leukemia were not available from our two patients for molecular or virologic studies (one patient died after the association was recognized and the other patient remains in remission). New cases of leukopenic T-PL that are identified clinically or histopathologically should be studied for evidence of HTLV-I and HTLV-II, so that the spectrum of virus-associated lymphoproliferative diseases may be defined further.

In summary, we have identified two cases of leukopenic chronic T cell leukemia with massive splenomegaly in which the leukemic cells resembled Galton's prolymphocytes. This leukemia can be differentiated from T-CLL and T-HCL on the basis of its distinctive cellular morphology. It also differs from classical T-PL by virtue of the leukopenia that is present before splenectomy. One patient (case 2) who was treated with splenectomy, died 23 months after clinical onset despite the subsequent addition of increasingly more aggressive chemotherapy. The other patient (case 1), treated with splenectomy and combination chemotherapy, is alive and clinically well after 24 months. These observations suggest the possible importance of early recognition of this distinctive leukopenic form of T cell leukemia, which, in contrast to HCL, appears to have an aggressive course similar to that in Galton's PL.

ADDENDUM

Since submission of our manuscript, three additional cases of HTLV-I-associated chronic lymphocytic leukemia have been reported,[62] although they were not leukopenic. Like our case 1, the patients were from Italy and, along with our case 1, confirm the widespread nature of HTLV-I-associated disease. These cases also suggest that Italy, particularly southern Italy, may be an endemic area for HTLV-I. Furthermore, our case 2, a black man from Los Angeles who had HTLV-II antibodies, was born and lived in the same general area as the first reported case of HCL from which HTLV-II was isolated.[61] A second such case was more recently reported by the same group of observers,[63] raising the possibility that HTLV-II-associated T cell lymphoproliferative disease may be endemic in the Los Angeles area.

Homozygous Hemoglobin Knossos ($\alpha_2\,\beta_2 27$(B9) Ala → Ser): A New Variety of β^+-Thalassemia Intermedia Associated With δ°-Thalassemia

By F. Baklouti, E. Dorléac, L. Morlé, P. Laselve, D. Peyramond, M. Aubry, J. Godet, and J. Delaunay

Hb Knossos (β 27 (B9) Ala → Ser) is a recently discovered hemoglobin variant endowed with β-thalassemic properties(1,2) We present the first homozygous cases. The propositus, a 19-year-old man is originally from northeast Algeria, but is unrelated to other Algerians who have hemoglobin Knossos. He has a β^+-thalassemia intermedia syndrome, including microcytic, hypochromic anemia, enlargement of the spleen, and an increase in the number of reticulocytes. The reduction of β-chain synthesis is pronounced (α/non α:2.76). Whole cells containing Hb Knossos have a dramatically low oxygen affinity (P_{50}:38 mm Hg). The propositus also has homozygous δ°-thalassemia. The chromosome carrying these mutations is characterized by the DNA haplotype I.

© 1986 by Grune & Stratton, Inc.

HB KNOSSOS (β27 (B9) Ala → Ser) in the heterozygous state has been recently recognized as the underlying abnormality in atypical β-thalassemia trait.[1,2] First identified in a family from Crete,[1] Hb Knossos was discovered soon afterwards in two families from northeast Algeria and in a family from the French West Indies.[3-5] In the heterozygous state, the Hb Knossos mutation causes "normal Hb A_2" β-thalassemia trait and, when associated with a "high Hb A_2" β-thalassemia trait or a Lepore fusion gene, generates a picture of β-thalassemia intermedia[1,3,5] The low amount[1,4] or absence of Hb A_2[5] has suggested that the β^{Knossos} gene is flanked by a δ°-thalassemic gene, at least in persons of mediterranean origin. We present the two first homozygous persons who have β^+-thalassemia intermedia associated with δ°-thalassemia.

MATERIALS AND METHODS

Case report. The propositus (II.1, Fig 1B), is a 19-year-old Algerian who has lived in France since 1982. He was born in Rabta, 80-km west of Setif in northeast Algeria. His parents are not consanguineous, but both originate from Rabta. The present family is apparently unrelated to the two Algerian families in which Hb Knossos was previously described.[3-5] Hematological abnormalities were discovered during evaluation for an unrelated orthopedic problem. Mild cutaneous pallor was noted. The spleen extended 1 cm below the costal margin. Radiological evaluation of the skeleton revealed abnormalities of the right humerus and the left femur, a C5 hemivertebra, and a L5 spina occulta, but the characteristic stigmata of thalassemia were absent. The red cell indices were RBC, 5.14×10^{12}/L, Hb, 10,1 g/dL; MCV, 52 fL (serum iron 4.5 μmol). Anisocytosis and target cells were present.

The sister (II.4) of the propositus is also a homozygote for Hb Knossos. She is 8 years old and asymptomatic. Neither icterus nor splenic enlargement were present. However, she had moderate anemia (Table 1). The parents and two brothers who were studied show a hematological picture characteristic of heterozygous Hb Knossos[1,3,4] (Table 1).

Methods. Hemoglobin analysis was performed by isoelectric focusing (IEF) according to Basset et al,[6] or on agarose gels provided by Sebia for Hb A_{1C} determination. Globin chains were analyzed by polyacrylamide gel electrophoresis (PAGE) in the presence of Triton X-100 and 8 mol/L of urea.[7] Gels were scanned at 570 nm. Hb A_2 was assayed using microchromatofocusing[8] and Hb F by the procedure of Betke et al.[9] γ-Chains were studied by Triton-urea PAGE[7] after alkali precipitation of Hb A and/or Knossos. α^A and β^{Knossos} chains from homozygotes were separated by ion exchange chromatography.[10] The β-chain was subjected to aminoethylation and to tryptic digestion.[11] The peptides were analyzed by fingerprinting[11] or reverse-phase high-performance liquid chromatography (HPLC) on a μ Bondapak C18 column (Waters, Milford, Mass) in a LKB system (Bromma, Sweden), using an increasing gradient of acetonitrile in 0.01 mol/L of ammonium acetate (pH 5.7), with a flow rate of 1.50 mL/min.[12,13] Amino acid composition of abnormal peptide βT3 was performed in a Biotronic amino acid analyzer. In vitro globin chain synthesis was carried out essentially according to Lingrel and Borsook.[14] Oxygen dissociation curves were performed in a Hemoscan differential spectrophotometer.

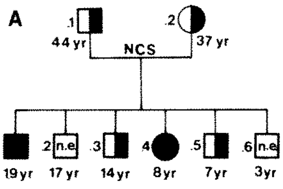

Fig 1. Pedigree of the family studied: □, β^A gene; ■, β^{Knossos} gene. Ages of family members are shown.

DNA was obtained from leukocytes as described[15] and was digested (10 to 15 μg) in the presence of restriction endonucleases, using conditions recommended by the manufacturers. DNA fragments were separated in 0.8% agarose gels, transferred to nitrocellulose filters,[16] and hybridized with ^{32}P-labeled probes. Four probes were used to recognize the seven polymorphic sites described by Orkin et al[17]: (a) a 1.3-(kb) *Bam* HI/*Eco*RI ϵ gene fragment in pBR 328; (b) a 0.8-kb *Pst* I/*Eco*RI Aγ IVS II in PSP 65; (c) a 1.7-kb $\psi\beta$ *Bgl* II/*Xba* I fragment in pBR 328; and (d) a 0.95-kb *Bam* HI/*Eco*RI β IVS II in pBR 322.

RESULTS

In the untransfused propositus (II.1), Hb A_2 was absent (Table 1, Fig 2a and c). Hb A was replaced by a component focusing slightly more cathodically (Fig 2a). This change became more apparent when IEF was carried out in agarose

II.1 and II.4 are homozygotes; ↗, propositus. The reason for the elevation of the reticulocyte count in I.1 is unknown.

*Determined by chromatofocusing.

†Determined by scanning of polyacrylamide-urea-Triton gels.

‡Normal values 2.69% ± 0.62% (n = 352).

§Normal values (n = 15): P_{50} = 27.20 ± 1.57 mm Hg; $\bar{n}$ = 2.69 ± 0.11; 2,3-DPG = 12.83 ± 1.90 μmol/gHb.

gels (Fig 2b). Electrophoresis in a polyacrylamide gel in the presence of Triton X-100 ascertained the existence of a β-chain variant in the homozygous state. Hb F was slightly increased with a $^{G}\gamma$ percentage of 21.1%. A similar picture was found in the second homozygote (II.4) (Table 1).

Further studies were carried out in the propositus. The in vitro synthesis of β-chains was depressed (α/non α = 2.76). P_{50} was dramatically increased (38 mm Hg) and $\bar{n}$ remained normal (Fig 3). Fingerprints of the abnormal β-chain appeared normal (Fig 4a), but high-performance liquid chromatography (HPLC) profiles allowed recognition of an abnormal peptide (Fig 4b). Amino acid analysis ascertained that the abnormal peptide was T3, with a serine residue in the place of an alanine residue (Table 2). These data identified the abnormal hemoglobin as Hb Knossos (β27(B9) Ala → Ser). The non-α globin gene cluster carried haplotype I (+ − − − − + +), the most frequently encountered haplotype among persons of mediterranean origin.[18]

In the parents and the two heterozygous brothers (II.3 and II.5), Hb A_2 was normal or slightly decreased (Table 1). Conventional IEF on polyacrylamide gel analysis failed to detect Hb Knossos revealed on agarose gel. Electrophoresis of Triton-urea gels showed that the precentage of the $\beta^{Knossos}$ chain in heterozygotes was remarkably homogeneous, but substantial variations of the $^{G}\gamma$ levels were found. However, since it can reasonably be assumed that the paternal and maternal Knossos chromosomes 11 are identical, the $^{G}\gamma$ percentages suggest that II.3 and II.5 have inherited the

normal chromosome 11 from their father. In the parents, the α/non-α ratios and the P_{50} were found to be moderately increased.

DISCUSSION

We described the third Algerian family with Hb Knossos.[3-5] To our knowledge, the propositus and her sister are the first recorded homozygous cases. The similarity of haplotypes associated with the Greek[18] and the Algerian mutations suggests that the same chromosome is involved among persons of northern and southern mediterranean origin, in contrast to the mutation found in blacks and in Creole people that is not flanked by a δ°-thalassemia gene and is associated with another haplotype.[19] Although it is not known on which side of the Mediterranean basin hemoglobin Knossos first arose, it is worth noting that the three Algerian families carrying this hemoglobin originate from a 200-km² region in northeastern Algeria. Given the apparently low frequency of the β^{Knossos} gene,[4] the detection of homozygotes in independent families would probably require a large scale screening of β^{+}-thalassemia intermedia patients in this part of Algeria.

The difficulty in detecting Hb Knossos must be emphasized. All families described to date that display Hb Knossos were discovered because of other β-chain abnormalities, β-thalassemia, Hb Lepore, or Hb S, facilitated demonstration of Hb Knossos. The present family was recognized by study of a homozygote. The association of a microcytosis with normal serum iron and an inconstantly decreased Hb A_2 usually suggests a mild form of α-thalassemia, but Hb Knossos should be considered and the appropriate screening technique should be used.

The present study of Hb Knossos homozygotes confirms the presence of a δ°-thalassemia gene in cis to the β gene mutation previously suspected[1,4] or demonstrated[5] among persons of mediterranean origin. δ°-Thalassemia has been described in different populations.[20-23] In homozygous cases,[22] a distinct δ°-thalassemia gene must be involved since the hematological data are not consistent with a homozygous Hb Knossos. No large deletion was found to be associated with the δ°-thalassemia gene cis to the β^{Knossos} gene.[5] Similarly, previous studies on δ°-globin genes have shown nondeletion defects.[23,24]

These two cases of homozygous Hb Knossos may be

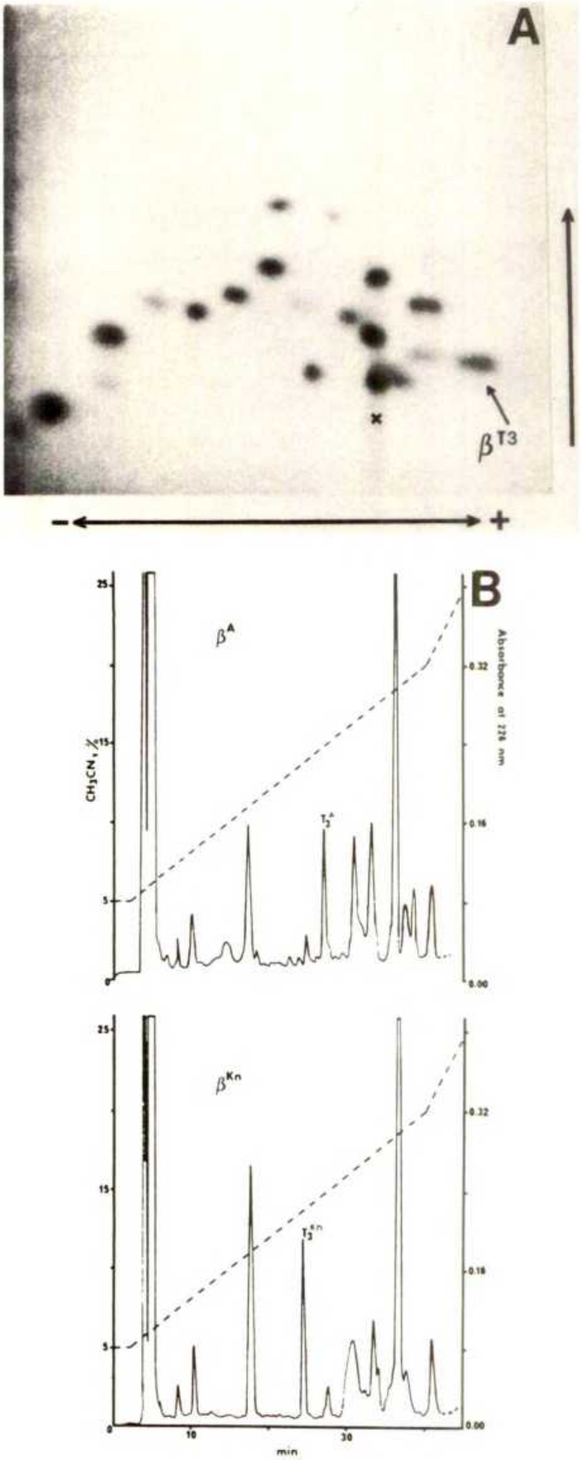

Fig 4. Peptide analysis: (A) tryptic digestion fingerprints; (B) high-performance liquid chromatography profiles of a control (top) and the propositus (bottom).

compared to Hb E disease. Both Hb Knossos and Hb E reflect mutations that also contribute to abnormal mRNA splicing.[18,25] The 8-year-old child (II.4) has significant anemia but is asymptomatic. The propositus had comparable anemia but the spleen was enlarged. Perhaps this condition may evolve into a more serious clinical syndrome as has been the case for the patient with Hb Knossos and Hb Lepore whom we recently described.[5] Homozygous Hb Knossos appears to be more severe than Hb E disease, which may reflect a more pronounced imbalance in globin chain synthesis (2.76 v 1.43 to 2.30 (n = 8)) (see refs. 26–28). Decreased oxygen affinity should reduce the clinical severity. Paradoxically, the β-thalassemia-$\beta^{Knossos}$ association is less severe[1,3] than the β-thalassemia-β^{E} association.[29]

The present report describes the two first cases of homozygous Hb Knossos in an Algerian family. This genotype produces the phenotype of β^{+}-thalassemia intermedia. The most salient features found in the propositus are the marked imbalance in globin chain synthesis, the reduced affinity of Hb Knossos for oxygen, and the association of the $\beta^{Knossos}$ gene with a δ^{0}-thalassemia gene and DNA haplotype I.

ACKNOWLEDGMENT

We thank Drs P. Brugiroux and J.L. Chiron for providing us with blood samples, Mrs C. Vianey-Liaud for performing the amino acid analyses, and Mrs M. Anzilutti for the preparation of the manuscript.

Defective Erythroid Progenitor Differentiation System in Congenital Hypoplastic (Diamond-Blackfan) Anemia

By Jeffrey M. Lipton, Michele Kudisch, Rachel Gross, and David G. Nathan

To explore the etiology of congenital hypoplastic or Diamond-Blackfan anemia (DBA) we investigated in vitro erythropoiesis in nine patients. Of the nine, seven were clinically responsive to prednisone. Four were infants evaluated at the time of diagnosis. Six were never or were only minimally transfused. Those for whom prednisone had been prescribed had discontinued the drug a minimum of five months prior to study. The bone marrows of these nine patients were compared with those of hematologically normal individuals and with those of four patients with transient erythroblastopenia of childhood (TEC) whose erythroid aplasia was as severe as that of the patients with DBA. Using the plasma clot semisolid culture technique to enumerate erythroid progenitors and to evaluate the growth characteristics of the colonies to which they give rise, we concluded that at the onset of DBA: (a) erythroid progenitor frequency does not correlate with the degree of anemia and erythroblastopenia; (b) erythroid progenitor differentiation may in some cases be abnormally insensitive to crude preparations of erythropoietin; and (c) progenitor erythropoietin insensitivity in vitro does not necessarily indicate prednisone insensitivity in vivo. Thus, DBA does not appear to be solely the result of deficient formation of erythroid progenitors but is, in addition, a disorder that is due to defective progenitor differentiation in vivo.

© 1986 by Grune & Stratton, Inc.

THE PATHOPHYSIOLOGY of congenital hypoplastic anemia or Diamond-Blackfan anemia (DBA) has remained obscure for >40 years. This rare macrocytic aregenerative anemia of childhood is characterized by moderate to severe anemia usually beginning in infancy. Other cell lines appear less affected, although mild neutropenia is occasionally observed and thrombocytosis is common. The bone marrow is characterized by normal cellularity with erythroid hypoplasia. Proerythroblasts are sometimes present, but erythroid differentiation is markedly diminished overall. Seventy-five percent of patients respond to prednisone, sometimes in vanishingly small doses, with complete or partial resolution of their anemia. Even in responsive patients the macrocytosis rarely disappears. The diagnosis and treatment of DBA has been thoroughly reviewed.[1,2]

In vitro culture of marrow mononuclear cells in semisolid media permits assessment of the apparent frequency of committed erythroid progenitors and, to a limited extent, their function.[3-5] By means of these culture techniques, the erythroid failure in DBA has been attributed to a severe[6] or moderate[7] deficiency of erythroid progenitors. This deficiency has been ascribed to failure of progenitors with pluripotentiality to differentiate into committed erythroid burst-forming units (BFU-E), the first step in the erythroid differentiation pathway. The studies that lead to these conclusions were performed on the marrows of prednisone-treated or multiply transfused older patients, however. Even in these studies, a qualitative dysfunction of erythroid progenitors, as manifested by a higher than normal erythropoietin requirement for terminal differentiation in addition to a quantitative deficiency of progenitors, was obtained. Further evidence for erythropoietin insensitivity was later provided by Chan and co-workers.[8,9] Therefore, we examined the marrows of newly diagnosed patients with DBA to determine the characteristics of DBA erythroid progenitor differentiation in the absence of the complications of therapy or the influence of disease chronicity. Five patients were examined at or near diagnosis. The study was carried out within two years of diagnosis in three of the remaining four patients, and all four had discontinued prednisone a minimum of five months prior to evaluation. Five of the patients were studied in infancy, and three more were studied within the first four years of life. One evaluated patient was an adult who had not been regularly transfused.

The results of this investigation of newly diagnosed patients have altered our concept of the pathophysiology of the disease. Although erythroid progenitor numbers as measured by their differentiation into colonies were lower than normal, particularly in steroid-resistant patients, we found them to be in excess of what was expected based on a precursor product relationship of progenitors to bone marrow erythroblasts and peripheral blood reticulocytes and much higher than what was reported in older, transfusion-dependent patients.[6] However, insensitivity of DBA progenitor differentiation to crude erythropoietin in vitro was found in both of the steroid-nonresponsive patients. Two of the steroid-responsive patients demonstrated a degree of crude erythropoietin insensitivity comparable to that of the nonresponsive patients, whereas three showed a mild to moderate degree of insensitivity and two had a normal response to crude erythropoietin in the system we use. On the basis of these results, we suggest that, at least at the onset of DBA, the initial stages of erythroid progenitor maturation proceed essentially normally from multipotent to committed erythroid progenitors. However, although the defect in three of the steroid-responsive patients was minimal, most patients do manifest an abnormality in the terminal differentiation of erythroid progenitors characterized by an insensitivity to crude erythropoietin. The extent of this erythropoietin insensitivity in vitro is quite variable and does not correlate with a

response to prednisone in vivo. Whether these findings are the result of an intrinsic progenitor defect or some other abnormality in the system that regulates terminal erythroid differentiation remains to be determined.

MATERIALS AND METHODS

Patients Bone marrow was obtained after informed consent was received from nine patients who fulfilled the diagnostic criteria for DBA.[1] The volume of all bone marrow aspirates was ~2 ml. The cell count after Ficoll-Hypaque density centrifugation[10] was in all cases >40 × 10^6 mononuclear cells per aspirate. Thus, contamination by peripheral blood mononuclear cells and dilution of progenitors by these cells was considered to be <10%. The timing of the studies with relationship to age, diagnosis, and treatment is shown in Table 1. Three of the steroid-responsive patients were initially studied at diagnosis, two were studied prior to administration of red cell transfusions, and one was studied after a single transfusion A fourth responsive patient was evaluated 18 months after diagnosis. She first received a brief course of androgens, followed by prednisone therapy with no transfusions. Two of the three other steroid-responsive patients were periodically transfused for seven months and 28 months, respectively, prior to this study. The remaining responsive patient, the only adult studied in this investigation, was transfused initially at diagnosis and received transfusions at the time of reinstitution of prednisone therapy after multiple elective cessations over a 20-year period. Of two steroid-nonresponsive patients, one was studied initially at diagnosis and before she received a transfusion, whereas the other was transfused approximately monthly for the 12 months prior to evaluation. Of the five patients previously treated with prednisone, all had discontinued the drug for a minimum of five months prior to evaluation. In addition to the normal marrows with which these studies of DBA marrow were compared, we also evaluated the marrows of four patients with transient erythroblastopenia of childhood or TEC. The patients were 12, 16, 19, and 21 months of age, respectively. They all had reticulocyte counts of <1.0% with hemoglobins of 4.0, 4.3, 6.1, and 4.0 g/dL, respectively. Spontaneous recovery of erythropoiesis occurred within one month of evaluation of all four cases.

Cell culture. Bone marrow low-density mononuclear cells prepared by Ficoll-Hypaque density centrifugation were plated at a cell density of 5 × 10^5/mL in the plasma clot culture system previously described[11] and modified.[12,13] The culture system contained from 0.1 U/mL to 4 U/mL of erythropoietin from various sources.* In some experiments, burst-promoting activity (BPA), the supernatant of the Mo cell line[14] kindly provided by Dr David Golde, was substituted for NCTC-109 (Microbiological Associates, Bethesda, Md) as 5% of the plasma clot culture. We find this source of crude BPA to be comparable to that derived from leukocyte-conditioned medium.

Clotting was initiated by the addition of 0.1 mL of NCTC-109 containing 1 U of grade I bovine thrombin (Sigma Chemical Co, St Louis). The 1.0 mL of clotting mixture was dispensed in 0.1-mL aliquots into 0.2-mL microtiter culture wells (Linbro plates, Linbro Scientific Co, New Haven, Conn) and incubated under 5% CO_2 in high humidity. The plasma clots were incubated for up to 14 days. The clots were fixed and stained as described by McLeod and co-workers.[11] Erythroid colonies in three to six clots were counted, and the results were expressed as the mean and SEM of the number of erythroid colonies per 10^5 cells plated. CFU-E were enumerated on day 7, and BFU-E were enumerated and scored according to size from 1+ to 4+ on days 11 through 14 as previously described.[13] Control marrows were obtained from hematologically normal individuals from three months of age to 50 years of age. Two were less than one year of age. The control studies were carried out during the time period in which this study was performed, frequently simultaneously, using identical tissue culture techniques.

RESULTS

Progenitor-derived colony enumeration. Previous data acquired in patients with long-standing DBA, of whom half were steroid resistant, suggested that the disorder in this group is characterized by a block in progenitor maturation at some point between the multipotent myeloid progenitor and the BFU-E stage of differentiation.[6] To evaluate this finding in the patients studied, erythroid progenitor-derived colonies were enumerated in plasma clot at 2 U/mL of erythropoietin. A degree of marrow erythroid aplasia far in excess of that predicted by the usual precursor product relationship of CFU-E to marrow erythroblasts provides strong evidence that in vivo progenitor maturation is relatively intact from the multipotent progenitor to the CFU-E stage of differentiation, and that the in vivo defect in DBA lies in the inability of CFU-E to differentiate beyond that stage. As shown in Fig 1, the mean and 1 SD of the frequency of CFU-E–derived colonies in DBA was lower than normal; however, normal frequencies were found in four of seven steroid-responsive patients. (The SEM for individual patients and controls was in the range of ±15% to 25%, in agreement with previous work using these culture techniques.[6]) The progenitor frequencies in the three remaining steroid-responsive patients, although low, were far in excess of that expected for the degree of reticulocytopenia. The cultures of marrows of the two steroid-nonresponsive patients provided relatively poor colony growth. CFU-E colony expression in the steroid-nonresponsive patients fell below 1 SD of the mean for the nine DBA patients. However, addition of a source of BPA to the latter cultures significantly enhanced their CFU-E–derived colony expression, suggesting that CFU-E are present in the marrow in sufficient numbers but that, in contrast to the less severely affected steroid-responsive patient, standard culture techniques do not overcome the block in differentiation to hemoglobin-containing cells unless BPA is added. The addition of BPA enhanced CFU-E–derived colony numbers in all five of the DBA marrows to which it was added. In contrast, the frequency of CFU-E–derived colonies was enhanced by BPA only in one apparently normal marrow. The marrow from this individual provided the only "normal" study in which CFU-E–derived colony frequency, in the absence of BPA, was below the normal range. Measurements of BFU-E–derived colony frequencies provided similar results. Three of the seven steroid-responsive patients had normal colony frequencies. BFU-E colony frequency was markedly increased in two of these patients and was moderately increased in a third steroid-responsive patient in the presence of BPA. Neither of the steroid-nonresponsive patients produced normal BFU-E–derived colony frequencies, and colony size was persistently deficient (1+ instead of 3 to 4+) in five of the cultures of the marrows of steroid-responsive patients and both steroid-nonresponsive patients. The significant enhancement of CFU-E–derived colony expression even for prednisone-resistant patients in the presence of BPA and BFU-E–derived colonies that were considerably smaller than those derived from normal controls strongly suggest that the failure of erythropoiesis results primarily from dysfunction of the terminal differentiation of erythroid progenitors rather than from their absence.

*The erythropoietin sources used in this study were: Sheep plasma, Connaught, Step III, Connaught Medical Research Laboratories, Willowdale, Ontario, Canada (Lot nos. 3029-1, 3031-1, 3032-1, 3039-1, 3042-1, 3076-1, and 3081-1), specific activity (sp. act.) 3 to 5 U/mg of protein; human urinary, National Heart, Lung and Blood Institute (NHLBI) (H-36-TaLSL), sp. act. 28 U/mg of protein; human urinary NHLBI (Arg-8-TaLSL), sp. act. 27 U/mg of protein; human urinary, NHLBI (E-8-39LSL), sp. act. 28 U/mg of protein; human urinary, Dr John Adamson, Seattle, sp. act. 30 U/mg of protein; human urinary, Dr Arthur Sytkowski, Boston, sp. act. 96 U/mg of protein; and human urinary, Toyobo Co, Ltd, Osaka, Japan, (Lot no. 1668), sp. act. 49 U/mg of protein.

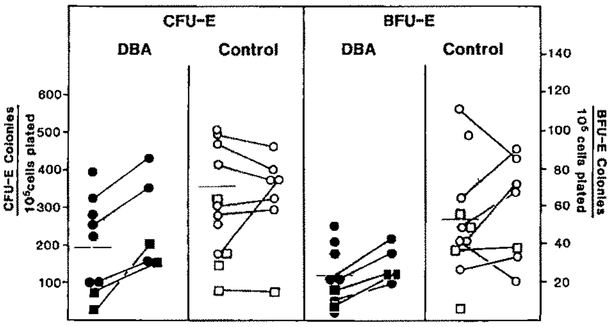

Fig 1. Erythroid progenitor-derived colony frequency in patients with Diamond-Blackfan anemia (DBA). CFU-E- and BFU-E-derived colonies are plotted on the left and right vertical axes, respectively, as colonies per 10^5 bone marrow cells plated. Steroid-responsive (●) and steroid-nonresponsive (■) patients with DBA are compared with hematologically normal controls (O) and patients with transient erythroblastopenia of childhood (TEC) (□). Shaded areas represent 1 SD from the mean for each group. TEC patients are not included in the mean colony counts and SD for the controls. Effect of burst-promoting activity (BPA) on colony frequency is shown on the horizontal axis.

Erythropoietin sensitivity of progenitor differentiation. There appears to be a complex system involving hematopoietic growth factors and cell–cell interactions that regulate the terminal differentiation of erythroid progenitors.[15] To gain further evidence of dysfunction of this erythroid progenitor differentiation system, we measured the crude erythropoietin requirement for in vitro DBA progenitor differentiation. To do so, we enumerated progenitor-derived colonies as a function of the erythropoietin concentration in the cultures. From these data, an erythropoietin dose-response curve was generated (Fig 2), and the [Epo]½max, that concentration of erythropoietin at which half the maximal number of progenitor-derived colonies are obtained, was determined. The abnormal dose-response curve shown in Fig 2 is one of two patient curves that do not approach a plateau level for erythroid progenitor-derived colony expression at or below an erythropoietin concentration of 4 U/mL. In this case, greater colony expression at a higher erythropoietin concentration would shift the [Epo]½max to an even higher value. As summarized in Fig 3, of the seven steroid-responsive patients, two had an abnormally high [Epo]½max for BFU-E and CFU-E indicative of

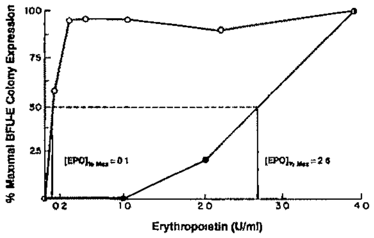

Fig 2. Representative erythropoietin dose-response curves in two patients with Diamond-Blackfan anemia (DBA) in the absence of exogenous burst-promoting activity (BPA). The percentage of maximal BFU-E colony expression on the vertical axis is plotted as a function of erythropoietin concentration from 0 to 4.0 U/mL on the horizontal axis for a patient with normal in vitro erythropoietin sensitivity (O—O) and a patient with low in vitro erythropoietin sensitivity (●—●). The concentration of erythropoietin at which there is 50% maximal BFU-E colony expression is defined as the half maximal erythropoietin concentration or [Epo]½max.

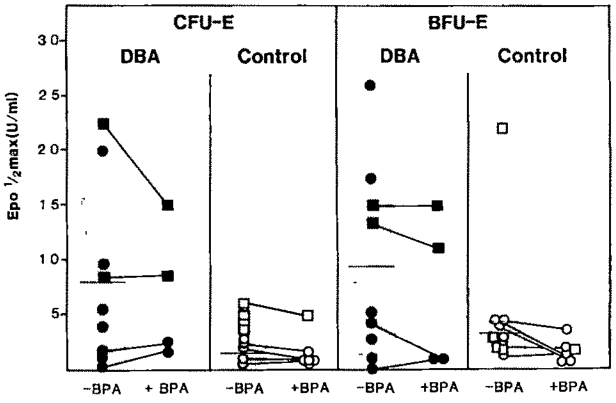

Fig 3. Half maximal erythropoietin concentration, [Epo]½max, the concentration of erythropoietin at which there is 50% maximal erythroid colony expression, in patients with Diamond-Blackfan anemia (DBA). The [Epo]½max for BFU-E and CFU-E plotted on the vertical axis for steroid-responsive (●) and steroid-nonresponsive (■) patients with DBA are compared with hematologically normal controls (○) and patients with transient erythroblastopenia of childhood or TEC (□). The shaded areas represent 1 SD from the mean for each group. TEC patients are not included in the mean colony counts and SDs the controls. The effect of burst-promoting activity (BPA) on the [Epo]½max is shown on the horizontal axis.

in vitro insensitivity to erythropoietin. Thus, five patients with steroid-responsive DBA had no evidence of a high erythropoietin requirement when compared with normal subjects and patients with TEC as described below. However, of these five, three had small (1+) BFU-E–derived colonies at two units of erythropoietin per milliliter. Both of the steroid-nonresponsive patients had an elevated [Epo]½ max and small progenitor-derived colonies. Although evaluated in only two abnormal patients, the presence of BPA did not normalize the [Epo]½max in steroid-resistant patients. In summary, an in vitro defect in the terminal differentiation of erythroid progenitors measured by an elevated [Epo]½max could be demonstrated in two of seven prednisone-responsive and in both prednisone-nonresponsive patients. Five steroid-responsive patients had progenitor differentiation that exhibited a normal [Epo]½max when compared with normal and TEC progenitors. Three of these patients and both steroid-resistant patients had small BFU-E–derived colonies. Two of the steroid-responsive patients exhibited normal erythropoietin sensitivity as measured by [Epo]½max and colony size. Table 2 summarizes DBA progenitor-derived colony enumeration and erythropoietin dose response data.

Progenitor colony enumeration and erythropoietin sensitivity in transient erythroblastopenia of childhood (TEC). To determine whether the findings in DBA were merely due to some unexpected and ill-defined result of severe anemia and erythroid hypoplasia, we pursued similar studies in patients with TEC, a spontaneously resolving red cell aplasia which initially is frequently indistinguishable from DBA.[2,16,17] Both syndromes are characterized by anemia, reticulocytopenia and elevated plasma erythropoeitin activity, and the absence of erythroid precursors in the marrow, but TEC is not familial and there are no associated congenital abnormalities. Erythroid failure in many TEC patients appears to be due to an IgG inhibitor directed against erythroid progenitors.[18,19] In agreement with the studies of Dessypris et al,[19] we confirm that progenitor colony enumeration in TEC yields variable results (Fig 1). One patient had normal CFU-E- and BFU-E–derived colony frequencies. Two patients had low numbers of CFU-E- and normal BFU-E–derived colony numbers, and a fourth TEC patient had low BFU-E and CFU-E colony frequencies. The presence of BPA had no effect on progenitor-derived colony expression in the one TEC patient so studied. The BFU-E [Epo]½max values in the three TEC patients with normal BFU-E-derived colony numbers were within the normal range. BFU-E colony morphology was normal (4+) in those three cases. The [Epo]½max for BFU-E–derived colonies in one patient was elevated, indicative of erythropoietin insensitivity. BFU-E–derived colonies in this case were small (1+). All TEC patients had mild to moderate elevations in [Epo]½max for CFU-E–derived colonies Thus, in the patients with TEC in whom anemia, reticulocytopenia, and bone marrow erythroid aplasia were comparable to that observed in DBA, erythroid progenitor behavior was different. BFU-E–derived colony frequency, morphology, and response to erythropoietin was normal in three of four patients, whereas CFU-E, although usually reduced in frequency, had an essentially normal in vitro response to erythropoietin. If one considers the minimal elevation in CFU-E [Epo]½max in TEC to be in some way related to the degree of erythroblastopenia observed in both TEC and DBA, both steroid-nonresponsive and two steroid-responsive patients clearly have a progenitor differentiation abnormality as measured by an abnormal [Epo]½max. These observations support the contention that the abnormal in vitro colony frequencies, morphology, and response to crude erythropoietin when observed in patients with DBA are actually due to defects in progenitor differentiation and are not caused by marrow erythroid hypoplasia and elevated plasma erythro-

poietin levels. In addition, the presence of a markedly abnormal erythropoietin dose response in one TEC patient and low CFU-E colony frequency in three TEC patients, supports the observation of Dessypris et al[19] that TEC is a heterogenous disorder which on occasion may mimic DBA.

DISCUSSION

Recent advances in experimental hematology have identified the existence of a pool of erythroid bone marrow progenitors which renew the morphologically identifiable precursor pool.[20-23] The trilineage myeloid progenitor is a cell capable of giving rise to granulocyte/macrophage and megakaryocyte progenitors and to the least mature erythroid progenitor, BFU-E. Under ordinary physiologic conditions in vivo this primitive cell divides and matures to form the next stage of progenitor development, the erythroid colony forming unit or CFU-E. The exact number of erythroid progenitors in human marrow is unknown because they are enumerated only in functional assays. Their differentiation in culture to "normal" numbers of colonies has been thought to indicate the presence of normal numbers of functional progenitors. The development of BFU-E and CFU-E into erythroid colonies has a characteristic pattern of in vitro sensitivities to erythropoietin. The program of differentiation of normal CFU-E is more sensitive to the hormone than is the system that controls the differentiation of BFU-E.[5,20-22]

Failure of erythropoiesis could result from defects at any of the steps in differentiation from progenitor to reticulocyte. Enumeration of progenitor-derived colonies has therefore been used in an attempt to define the level of erythropoiesis that is inhibited in DBA. Nathan et al[6] studied erythroid progenitor-derived colony numbers in a series of patients with DBA, most of whom had had the disease for at least five years and were either transfusion dependent or taking prednisone. None were evaluated at the time of diagnosis. The absence of detectable BFU-E in this group of patients led these investigators to conclude that the defect arises at an early step, the commitment of trilineage progenitors to BFU-E. Freedman and co-workers detected patients with normal as well as low numbers of CFU-E.[7] BFU-E were not measured, and the relationship of the studies to the time of diagnosis was not specified. Variable results have been reported in smaller studies.[8,9,24-26] Nathan et al[6] and Chan et al[8] also demonstrated that the progenitors of some patients with DBA exhibit relative erythropoietin insensitivity. In some of these cases, the erythropoietin dose response could be normalized somewhat by the administration of prednisone in vivo[6] or even in vitro,[8] suggesting to Chan and co-workers[8,9] the possibility that the degree of erythropoietin insensitivity and the response to prednisone in vitro might correlate with a clinical steroid response. The exact mechanism of this in vitro abnormality in progenitor differentiation remains controversial. An intrinsic progenitor defect may be the cause, but other workers have suggested that red cell failure in DBA is caused by the suppression of erythroid differentiation by cytotoxic or autoreactive T lymphocytes[27,28] or by a bone marrow microenvironmental defect.[24] In addition, other abnormalities of lymphocyte function have been observed in this disease.[29] Abnormal lymphocyte function suggests that a suppressor mechanism may be operative. However, transfusion sensitization could explain these results.[30,31] Other investigators have shown that peripheral blood T cells from patients with DBA are able to induce in vitro erythropoietin-dependent BFU-E colony expression as do normal T cells[32] and have no suppressor function.[6,33] One group of investigators appears to have identified a serum factor that inhibits erythropoiesis in DBA,[34] but further attempts to identify such humoral inhibitors have not been successful,[7,24,35] in contrast to the findings in TEC.[18,19]

In this study, erythroid progenitor-derived colonies from patients with DBA were enumerated in cultures containing erythropoietin at a concentration of 2 U/mL. The mean colony frequency observed in DBA was lower than the mean of normal controls and the steroid-resistant patients had values in the lowest range, although the addition of BPA significantly enhanced their CFU-E colony expression. However, if one concludes that a significant frequency of committed progenitors, especially CFU-E, indicates a relatively intact pathway of differentiation from trilineage to committed progenitors, there does not appear to be an in vivo defect in progenitor maturation, especially in early cases of steroid-responsive DBA, that is significant enough solely to account for the observed degree of anemia and reticulocytopenia.

To determine the presence of a functional defect in the erythropoietin-dependent differentiation of DBA progenitors, both colony size and a progenitor erythropoietin dose response was evaluated in each patient studied. Results showed that seven of nine patients had an abnormality in the terminal differentiation of progenitors to colonies of hemoglobinized cells, characterized by these measures of insensitivity to erythropoietin. Although both patients who were refractory to prednisone therapy had abnormal dose responses to crude erythropoietin and small BFU-E–derived colonies, the presence of two responsive patients with identical in vitro abnormalities and three with small BFU-E–derived colonies but a normal erythropoietin dose response indicates that DBA is a heterogenous disorder in which abnormal progenitor differentiation in response to crude erythropoietin using the culture system we use is common. The variation in severity does not necessarily correlate with a lack of clinical responsiveness to prednisone therapy.

The study of bone marrow erythroid progenitors from patients with TEC provides an evaluation of progenitor frequency and differentiation in response to erythropoietin in the face of a level of anemia, reticulocytopenia, and bone marrow erythroid aplasia similar to that seen in DBA. In three of four patients studied, we were able to demonstrate normal BFU-E colony morphology and response to erythropoietin. CFU-E colonies were deficient in three of four TEC patients. The [Epo]½max in these cases was mildly elevated. The defect in two steroid-responsive and in both nonresponsive DBA patients was far in excess of this mild abnormality. We therefore conclude that the normal progenitor frequencies observed in DBA were not due to a concentration artifact and that the abnormal response to erythropoietin in DBA is not merely an epiphenomenon associated with a high degree of erythroid aplasia.

A large body of data suggests that the defect in erythroid differentiation in DBA is a consequence not of an intrinsic progenitor abnormality such as a decreased or abnormal responsiveness to erythropoietin and/or BPA, but of the extrinsic suppression of progenitor differentiation.[24,27,28] Although it is possible that high levels of these mediators may overwhelm a suppressor mechanism, the requirement in severe cases for exogenous BPA to induce the terminal differentiation of DBA CFU-E in vitro and the relative insensitivity of the system to crude erythropoietin also suggest that there could be defective BPA production by DBA marrow accessory cells. The addition of high concentrations of crude erythropoietin may even enhance colony expression in less severe cases by providing exogenous BPA. Thus, the use of impure erythropoietin preparations containing BPA may have obscured an in vitro defect in the progenitor differentiation system in the steroid-responsive patients. Recently, we have been able to fractionate normal marrow into a highly enriched progenitor population and three distinct accessory cell populations.[36] When this system was used, normal CFU-E removed from all sources of BPA have been shown to require small amounts of exogenous BPA to induce erythropoietin-dependent differentiation. The data presented in this study demonstrate that congenital hypoplastic or DBA is a heterogenous disorder. There appears to be no significant block in erythroid maturation from the trilineage myeloid progenitor to CFU-E. However, there is instead a defect in the terminal differentiation system of erythroid progenitors. This observation and further data demonstrating an abnormal response of some DBA progenitors to crude erythropoietin and BPA provide the essential framework for more definitive studies. We should now be able to examine the response of highly enriched progenitors to pure preparations of erythropoietin and BPA and to evaluate bone marrow accessory cell function in DBA. These studies, based on the data presented here, will allow for a more precise understanding of the apparently diverse pathophysiology of DBA.

ACKNOWLEDGMENT

We are indebted to Dr John Adamson, University of Washington and Drs Peter Dukes and Anne Ball, Blood Disease Research, Division of Blood Diseases and Resources, National Heart, Lung and Blood Institute (NHLBI), Bethesda, Md and to our colleague, Dr Arthur Sytkowski, for samples of human urinary erythropoietin. We thank Ms Pearl Leavitt for performing the bone marrow differentials. We owe a particular debt of gratitude to Dr Janell Ferguson for her support of this work and to Drs John Truman and Peter Newberger for their continuing referral of patients. Special thanks to Liana Apelis for her expert preparation of this manuscript.

Plasma Clearance Rates of Coagulation Factors VIII and IX in Factor-Deficient Individuals

By Dennis A. Noe, William R. Bell, Paul M. Ness, and Jack Levin

The plasma clearance rates of factors IX and VIII were determined in patients with hemophilia A and B who had received factor replacement by prolonged, continuous infusion of factor concentrates. The clearance rates were calculated by dividing the factor infusion rates by the steady-state plasma factor activities corrected for baseline factor activities. The mean factor IX clearance rate in eight factor IX-deficient patients was 233 mL/h (range 159 to 340 mL/h). The mean normalized clearance rate was 3.4 mL/h/kg. The mean factor VIII clearance rate in eight factor VIII-deficient patients was 294 mL/h (range 229 to 361 mL/h) and the mean normalized rate was 5.0 mL/h/kg. Both factors show linear relationships between the factor infusion rates and the steady-state plasma factor activities achieved.

© 1986 by Grune & Stratton, Inc.

THE DISAPPEARANCE of procoagulant factors IX and VIII from the plasma of factor-deficient individuals receiving replacement therapy is usually described in terms of first-order elimination rate constants or half-lives.[1] However, both of these kinetic parameters are hybrid measures that depend as much on the volume of distribution of a factor as they do on the rate of elimination of the factor.[2] The plasma clearance rate of a factor, on the other hand, is the primary kinetic parameter that uniquely measures the net removal of the factor from the plasma.[3] In addition, because the plasma clearance rate is a model-independent measure, no assumptions need be made concerning the distribution of a factor in the body or its sites of metabolism or excretion.[4,5] Hence, clearance rate is the logical and preferable way to quantify the disappearance from plasma of the coagulation factors because details concerning distribution, metabolism, and excretion of the factors are unknown.

There are two experimental approaches to the measurement of the plasma clearance rate of a substance.[2] One method is to administer an intravenous (IV) bolus dose of the substances and then to construct its plasma concentration *v* time curve. The clearance rate is calculated by dividing the dose by the area under the curve. In the other method, the substance is infused IV at a constant rate until the steady state is achieved. In this case, the plasma clearance rate equals the infusion rate divided by the steady-state plasma concentration. We have used this relationship to estimate the plasma clearance rates of factors IX and VIII in factor-deficient individuals who received factor replacement therapy in the form of prolonged, continuous infusions of factor concentrates.

MATERIALS AND METHODS

Subjects From 1978 to 1982, many of the factor VIII- and factor IX-deficient patients admitted to The Johns Hopkins Hospital participated in a clinical study in which they received factor replacement therapy using a continuous infusion protocol.[6] This therapeutic approach was used to achieve constant plasma factor levels rather than the varying levels that result from an intermittent dosing regimen. The patients who were treated with this protocol were identified by a search of the medical records maintained by the Division of Hematology. The pertinent demographic, clinical, and laboratory data on these patients were extracted from the individual medical records. Patients with antifactor antibodies were excluded. This study was approved by the Joint Committee on Clinical Investigation of The Johns Hopkins University School of Medicine.

Factor infusion protocol. At least one and sometimes multiple pretreatment blood specimens were collected and assayed for plasma factor activity The patients received two to 16 bolus doses of reconstituted factor concentrate (factor IX concentrate: Konyne, Cutter Laboratories, Berkeley, Calif; factor VIII concentrate: Factorate, Armour Pharmaceutical Company, Kankakee, Ill) on an every-12-hour schedule prior to the start of continuous infusion therapy. The doses of concentrate administered were those believed to be appropriate in the respective clinical situations. The factor content of the concentrate doses were calculated from the manufacturers' stated product content times the volume of concentrate infused. Blood specimens for plasma factor activity determination were drawn ~15 minutes before and 15 to 30 minutes after each dose.

The last of the bolus doses served as a loading dose, immediately after which the continuous infusion of factor concentrate was started. The rate of infusion of concentrate was selected so that the total daily factor activity infused would be equal to that given during the intermittent bolus dose regimen. Each container of infusate was administered over 12 hours; therefore, adequate concentrate to provide one half of the daily total factor activity appropriate for the patient was prepared and placed in the infusion solution The infusion solution was 1 L of 0.2 mol/L of NaCl, 5% dextrose solution, packaged in a polyvinyl plastic bag. The rate and constancy of administration was controlled by a volumetric displacement pump (Abbott/Shaw LifeCare IV Pump, Model II, Abbott Laboratories, North Chicago). Continuous infusion therapy lasted from 60 to 312 hours. Blood specimens were drawn 10 to 30 minutes after the start of each container of infusate and approximately ten minutes prior to the termination of each container. The specimens were obtained by venipuncture of the arm that did not receive the infusion. The infusions were discontinued when indicated clinically. Plasma samples were drawn approximately every six hours after discontinuation of replacement therapy until factor levels of <0.1 U/mL were detected. Factor activities were assayed in all the blood specimens.

Kinetic analysis The plasma clearance rate of the factors was calculated by dividing the factor infusion rate by the corrected steady-state plasma factor activity. plasma clearance rate = infusion rate/steady-state factor activity. Steady-state factor activity was defined as the average of three to five plasma factor activities

measured once the factor levels had reached an apparent plateau during continuous infusion therapy. The corrected steady-state factor activity equalled the steady-state factor activity minus the baseline factor activity. The average of a patient's pretreatment factor levels constituted the baseline activity.

Analytical methods. Routine procedures for blood collection, sample preparation, and plasma factor assays were used in our patients. Blood was collected in 5-mL samples in plastic tubes containing 0 5 mL of 0.13 mol/L of sodium citrate Within 30 minutes of collection, the samples were centrifuged at 1,800 g for ten minutes, rendering the plasma platelet-poor. The plasma supernates were transferred to plastic tubes and immediately placed into storage at −20°C. Factor assays were performed within 72 hours. Factor VIII and factor IX activities were quantified by one-stage clotting-time bioassays using factor VIII- and factor IX-deficient plasma, respectively, as substrates.[7] The factor deficient plasmas were obtained by plasmapheresis of patients with severe congenital factor deficiencies as determined by family and clinical histories and corroborating laboratory studies. Single clotting-time determinations for sample plasmas were compared with the clotting time *v* plasma concentration dose-response curves for normal, pooled plasma. Sample coagulant activities were interpolated from the control plasma curves as graphed on double logarithmic paper. Normal plasma was obtained from healthy blood bank donors with normal prothrombin and partial thromboplastin times The plasma pools consisted of plasma from 60 to 120 donors. One unit of factor per milliliter was defined as the factor activity in normal human plasma.

RESULTS

Eight factor IX-deficient patients and eight factor VIII-deficient patients were identified as having received factor replacement by continuous infusion of factor concentrate. In every case, replacement therapy was administered either to control a bleeding episode or to provide hemostatic factor levels during and after a surgical procedure. Among the factor IX-deficient patients, 3 had received 1 course of continuous infusion therapy, 3 had 2 courses, 1 had 3 courses, and 1 had 6 courses (Table 1). Among the factor VIII-deficient patients, 6 had received a single course of continuous infusion therapy, 1 had 2 courses, and 1 had 3 courses (Table 2). For 5 of the patients, some or all of the courses of therapy had been conducted during a single hospital stay.

Clearance rate. Apparent plateaus of plasma factor activity were achieved in all patients after two to five days of therapy. However, three factor IX-deficient patients and three factor VIII-deficient patients exhibited substantial day-to-day variability in their steady-state factor activities (i.e., a range of values ±25% of the mean value). The ranges in these patients, expressed as a percentage of their mean plasma activities, were ±30%, 34%, and 69% for the factor IX-deficient patients, and ±36%, 41%, and 47% for the factor VIII-deficient patients. The factor clearance rate for each patient was calculated by averaging the clearance rates determined from each of the infusions administered to the patient.

The factor IX clearance rates ranged from 159 to 340 mL/h (normalized for body weight: 1.9 to 5.8 mL/h/kg) with a mean value of 233 mL/h (3.4 ml/h/kg). The clearance rates do not correlate with body weight ($r = -.17$) or body surface area[8] ($r = -.13$). The factor VIII clearance rates ranged from 229 to 361 mL/h (3.5 to 5.9 mL/h/kg) with a mean rate of 294 mL/h (5.0 mL/h/kg). The correlations with body weight ($r = .50$) and body surface area ($r = .60$) are not significant.

Dose response. The relationships of the corrected steady-state factor activities to the rates of factor infusion were studied by least-squares linear regression analysis. The results of all of the studies were analyzed. The regression equation for the dose response to factor IX is: corrected steady-state factor IX activity = 0.08 + 0.0034 × factor IX infusion rate (factor IX activity in U/mL, rate in U/h). The regression is statistically significant ($r = .81$, $P < .001$) and, as shown in Fig 1, fits the data well (SE of the estimate = 0.10 U/mL). The analysis of variance of the regression indicates that 65% of the variation in steady-state factor IX activities is attributable to the different infusion rates. Conversely, 35% of the variation is unexplained. Separate regression analysis of the study data from patient 5 indicates that intraindividual variability accounts for >65% of the total unexplained variation. The possibility that variability in body weight accounts for some of the unexplained interindi-

8	56	175	1.65	51	0 16	319

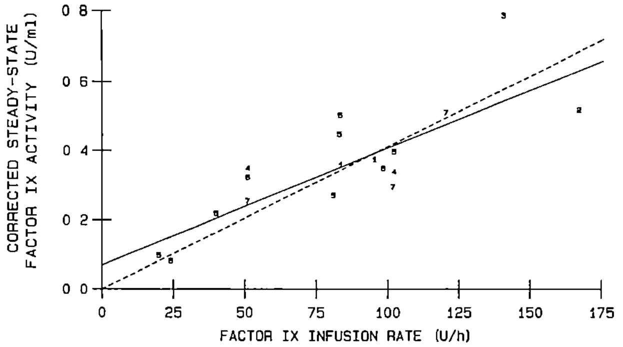

Fig 1. Relationship of the corrected steady-state factor IX plasma activity to the factor IX infusion rate during continuous infusion therapy. The regression line (—) and the regression line passing through the origin (- -) are shown.

vidual variance was tested by regression of the steady-state factor activities on the individual infusion rates divided by the patient's body weight. This approach did not produce a better fit of the data (r = .78; SE of the estimate = 0.10 U/mL).

The regression equation describing the factor VIII dose response is: corrected steady-state factor VIII activity = 0.06 + 0.0030 × factor VIII infusion rate (factor VIII activity in U/mL, rate in U/h). This regression also achieves statistical significance ($r = .91$, $P < .001$) and fits the data well (SE of the estimate = 0.07 U/mL), as shown in Fig 2. Here, the variability in the infusion rates accounts for 76% of the variation in steady-state factor VIII activities. As with the factor IX data, normalizing the factor VIII infusion rates for body weight did not result in an improved fit of the data (r = .87, SE of the estimate = 0.09 U/mL).

Ordinary linear regression analysis generates equations that have nonzero intercepts. The presence of a constant term allows the equations to fit the data better but, as in this case, does not strictly adhere to the form of the physiologic model. Because neither of the constant terms in the ordinary regression lines were significantly different from zero, the data were reexamined by a linear regression analysis in which the fitted lines were forced to pass through the origin. The resulting equations are: corrected steady-state factor IX activity = 0.0042 × factor IX infusion rate (factor IX activity in U/mL, rate in U/h); and corrected steady-state factor VIII activity = 0.0035 × factor VIII infusion rate (factor VIII activity in U/mL, rate in U/h).

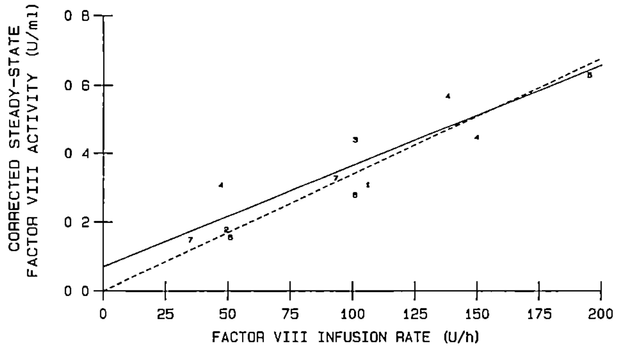

Fig 2. Relationship of the corrected steady-state factor VIII plasma activity to the factor VIII infusion rate during continuous infusion therapy. The regression line (—) and the regression line passing through the origin (- -) are shown.

As shown in Figs 1 and 2, over the range of factor activities achieved in this study, these equations differ very little from those found by ordinary regression analysis. In addition, these equations are essentially identical to those which result from rearrangement of the clearance model equation (first equation) and substitution of the appropriate mean factor clearance rates: corrected steady-state factor IX activity = 0.0043 × factor IX infusion rate (factor IX activity in U/mL, rate in U/h); and corrected steady-state factor VIII activity = 0.0034 × factor VIII infusion rate (factor VIII activity in U/mL, rate in U/h).

The excellent fit of the data confirms the validity of the clearance equation as a mathematical model of factor kinetics during continuous infusion therapy.

DISCUSSION

The reliability of an estimate of the plasma clearance rate of a substance determined with the continuous infusion method depends on accurate measurement of the dose administered and the plasma concentrations achieved. The factor activities in this study were measured by experienced technicians using a standard, quality-controlled, one-stage bioassay.[7] Optimal specimen collection and handling techniques were used and the plasma specimens were stored for <72 hours prior to being assayed. Therefore, there is no reason to suspect any systematic error in the measurement of the factor concentrations.

Because of the retrospective nature of this study, it was necessary to calculate the factor infusion rates by using the manufacturers' stated product content of factor in the concentrates. It would have been preferable to have measurements of the factor contents of the infusates. A number of studies have found that the stated potencies of the high-purity concentrates used in these patients are accurate, however.[9-11] The factor IX concentrate has also been found to contain a minimal amount of activated factor IX.[12] The factor concentrates have also been found to be stable for at least 12 hours when kept at room temperature. This is true for the factor IX concentrate in its reconstituted form, as stated in the product insert (Document 14-7620-203; rev Sept 1978), and for the factor VIII concentrate in dilute solution, the condition under which it was administered in this study.[13]

An additional concern in the measurement of clearance rates using the continuous infusion method is that the plasma concentrations must be measured when the substance is in steady state. If they are measured when the substance is still accumulating in the body, the clearance rate will be underestimated. In this study, the factor activities two to five days after the beginning of infusion therapy were taken to represent the steady-state factor concentrations. During that interval, the activities appeared to have reached a steady-state plateau; ie, the activities were not continuing to increase, although at times there was appreciable day-to-day variability in the measured activities. In addition, by using published descriptions of the bolus kinetics of factor IX[14] and VIII,[1] it can be calculated[15] that factor IX will have reached at least 95% of its steady-state value by 102 hours following the beginning of infusion therapy, and factor VIII will have reached 95% of its steady-state value by 60 hours. Both of these times are within the sampling interval chosen on empirical grounds in this study.

Further evidence that the clearance rate calculations in this study are valid is that the estimates agree with others in the literature. The normalized estimate of the plasma clearance rate of factor VIII, 5.0 mL/h/kg, is close to the rates that can be calculated from two studies of the bolus dose kinetics of factor VIII concentrate. In six patients receiving each of three brands of concentrate, the average clearance rate was 5.5 mL/h/kg.[16] In another 35 patients, each receiving one of three brands of concentrate, the average clearance rate was 3.9 mL/h/kg.[17] The present estimate is also very close to the rate that can be calculated from the data in a report of the dose response of five children to continuous factor infusion therapy using cryoprecipitate and factor concentrate,[13] 5.3 ml/h/kg. The plasma clearance rate of factor IX that can be derived from a study of the bolus dose kinetics of factor IX concentrate in seven patients is 5.0 mL/h/kg.[18] This value compares favorably with the normalized clearance rate in the patients reported here, 3.4 mL/h/kg, although the agreement is not as close as that among the factor VIII clearance rates. In a study of the bolus dose kinetics of radiolabeled factor IX, the clearance rate of factor IX in three patients was found to be 5.3 mL/h/kg (the clearance rate in a fourth subject was much higher, 10.5 mL/h/kg).[19]

ACKNOWLEDGEMENT

The authors wish to acknowledge the Armour Pharmaceutical Co, which supported the original clinical study of the patients described in this report, and Daniele Cornell for expert technical assistance.

B Lymphoblastoid Cell Lines With Normal and Defective O-Glycosylation Established From an Individual With Blood Group T_n

By Carl G. Gahmberg, Liisa Peltokorpi, and Leif C. Andersson

Individuals with the T_n blood group contain terminal serine/threonine-linked *N*-acetylgalactosamine residues in their blood cells. This is due to lack of UDP-D-galactose: D-*N*-acetyl galactosamine β-D-galactosyl transferase from part of their red cells and probably from their leukocytes. We have established B lymphoblastoid cell lines from such an individual by in vitro infection of his lymphocytes with Epstein-Barr virus. The original line contained a mixture of cells reactive and nonreactive with *Helix pomatia* lectin (Hp). These cells were subcloned after staining with fluorescent Hp by a fluorescence-activated cell sorter (FACS) into homogeneous, phenotypically stable lines of Hp-positive (Hp+) and Hp-negative (Hp−) cells. The molecular differences between the membrane glycoproteins were characterized by carbohydrate-specific surface labeling techniques, Hp affinity chromatography, polyacrylamide slab gel electrophoresis and glycopeptide/oligosaccharide analysis. The major O-glycosidic membrane glycoprotein (GP105) was retained on Hp-Sepharose columns only from Hp+ cells, whereas the common leukocyte antigen (GP160–200) was partially retained on Hp columns from both lines. These proteins were isolated by immune precipitation with monoclonal antibodies and characterized. The results show that the GP105 glycoprotein from Hp+ cells contains terminal *N*-acetylgalactosamine residues but also more complex oligosaccharides. The common leukocyte antigen showed different electrophoretic mobilities in Hp+ and Hp− cells. UDP-galactose D-*N*-acetyl galactosamine β-galactosyl transferase was almost absent in the Hp+ cells. These cell lines are useful for studies on the functional role and regulation of the biosynthesis of O-glycosidic carbohydrates.

© 1986 by Grune & Stratton, Inc.

PROTEINS expressed at the surface of mammalian cells are almost always *glyco*proteins.[1] Two major types of carbohydrate structures exist in membrane glycoproteins: asparagine-linked *N*-glycosidic oligosaccharides and serine/threonine-linked O-glycosidic oligosaccharides.[2] In contrast to the relatively large amount of information available on the structure, biosynthesis, and function of *N*-glycosidic carbohydrates, little is known about the biosynthesis and function of O-glycosidic carbohydrates in cell surface glycoproteins.

Structural/functional relationships can be elucidated by use of cellular mutants with impaired glycosylation. Under the selection pressure with various toxic plant lectins or specific antisera against surface molecules, mutant cell clones that lack defined carbohydrate structures have been obtained.[3,4]

Instead of using these methods of selection, another approach would be to immortalize naturally existing cellular mutants. Red cell membranes from individuals with the T_n blood group lack UDP-galactose: *N*-acetyl D-galactosamine β-D-galactosyl transferase.[5,6] Platelets and hematopoietic precursors from T_n-positive individuals are reactive with the *N*-acetyl galactosamine-specific *Helix pomatia* lectin (Hp), indicating a glycosylation change in these cells resulting from a similar enzyme deficiency.[7,8]

We have now established a lymphoblastoid cell line by in vitro Epstein-Barr virus infection of blood lymphocytes from a person with the T_n blood group. Approximately 40% of cells in the original cell line reacted with the Hp lectin. Here we report that the cloned subline consisting of Hp+ cells contains almost no O-galactosyl transferase activity, which results in incomplete O-glycosylation of the major membrane sialoglycoprotein and T_n blood group activity. This cell line should be useful for studies on the function of O-glycosidic carbohydrate.

MATERIALS AND METHODS

Establishment of lymphoblastoid cell lines. Mononuclear leukocytes were isolated by Ficoll-Isopaque density centrifugation from 20 mL of heparinized blood of normal individuals and an individual with the T_n blood group. This individual with blood group O had ∼33% apparently normal red cells and 67% with lower electrophoretic mobility.[9] The isolated blood mononuclear leukocytes were treated for three hours with culture supernatants from the marmoset cell line 95-8, which produces infectious Epstein-Barr virus.[10] The cells were cultivated in RPMI 1640 medium supplemented with 10% fetal calf serum (FCS) (Flow Laboratories, Glasgow, Scotland). After approximately one month, lymphoblastoid cells growing in characteristic aggregates were observed.

Isolation of Hp-reactive and nonreactive lymphoblastoid cells. Hp was obtained from Pharmacia (Uppsala, Sweden). An aliquot was labeled with fluorescein using fluorescein isothiocyanate (FITC).[11] The mixture of Hp-reactive (Hp+) and Hp-nonreactive (Hp−) cells was fractionated using FITC-labeled Hp and a FACS IV (Becton Dickinson, Oxnard, Calif). The Hp+ and Hp− cells were further cultured as described above. The cells were studied by fluorescence using labeled Hp and a Zeiss Universal fluorescence microscope.

Cell surface labeling of lymphoblastoid cells. Approximately 50×10^6 cells were labeled with ^3H by treatment with *Vibrio cholerae* neuraminidase (Koch-Light, Haverhill, Suffolk, England) plus galactose oxidase (Sigma, St Louis), or galactose oxidase only, followed by reduction with NaB^3H_4 (8 to 15 Ci/mmol, The Radiochemical Centre, Amersham, England) as described in detail previously.[12] Sialic acid-containing glycoconjugates were labeled by the periodate/NaB^3H_4 surface-labeling technique.[13] After being labeled, the cells were washed in 0.15 mol/L of NaCl to 0.01 mol/L of sodium phosphate, pH 7.4 (PBS) and lysed at 0 °C in PBS containing 1% Triton X-100, 1% ethanol, and 2 mmol/L of phenyl-

methylsulfonyl fluoride (Sigma). The samples were centrifuged at 10,000 g for 30 minutes and used for subsequent analyses.

Affinity chromatography of radioactively surface-labeled glycoproteins. Periodate/NaB^3H_4-labeled Hp+, Hp− and lymphoblastoid cells from normal individuals were solubilized in Triton X-100-containing buffer, and extracts corresponding to 5×10^6 cells were applied to Hp-Sepharose columns (Pharmacia). After being washed with the Triton X-100-containing buffer, adsorbed glycoconjugates were eluted with this buffer containing 10 mmol/L of D-*N*-acetyl galactosamine. Two-mil fractions were collected, and 25-μL aliquots were counted for radioactivity in a Triton X-114-based scintillation fluid. The passed-through and sugar-eluted peak tubes were separately combined and used for subsequent analysis.

Immunoprecipitation. Immune precipitation was performed as described[14] with some modifications. Surface-labeled cell extracts were preincubated with 0.1 mL of a 10% suspension of protein A-containing *Staphylococcus aureus* cells (Cowan I) for 30 minutes at 0 °C. After centrifugation, the supernatants were recovered and incubated for two hours with the L10 monoclonal antibody[15] or with a monoclonal antibody against the common leukocyte antigen (New England Nuclear, Boston). Then, 5 μL of rabbit anti-mouse IgG was added (Dakopatts, Copenhagen, Denmark), and the incubation was continued for one hour. *S aureus* cells (0.2 mL of the 10% suspension) were added and, after 30 minutes, the bacteria were washed, and the adsorbed antigens were eluted by boiling in 1% sodium dodecyl sulfate (SDS). Aliquots were counted for radioactivity, and the rest were used for gel electrophoresis and glycopeptide/oligosaccharide analysis.

Polyacrylamide slab gel electrophoresis. Polyacrylamide slab gel electrophoresis of radioactively labeled cell extracts was performed according to Laemmli[16] using 8% acrylamide gels. The gels were treated for fluorography according to Bonner and Laskey.[17] ^{14}C-Labeled standard proteins were obtained from the Radiochemical Centre, Amersham. Kodak X-Omat AR film was used.

Analysis of glycopeptides/oligosaccharides. ^3H-Surface-labeled samples from the Hp-Sepharose eluates or immune precipitates were digested with 10 mg/mL of protease from *Streptomyces griseus* (Pronase) (Sigma). The samples were incubated in 0.1% SDS in Dulbecco's PBS for 24 hours at 60 °C. After lyophilization, the alkali-labile oligosaccharides were liberated by treatment with 0.05 *N* of NaOH and 1 mol/L of $NaBH_4$ for 16 hours at 45 °C.[18] After neutralization with acetic acid, the samples were lyophilized and analyzed on a Biogel P-6 column in 0.1 mol/L of NH_4HCO_3 and 0.1% SDS. Blue dextran was added to each run to determine the position of the void volume. Aliquots of the fractions were counted for radioactivity. Standards were: *N*-acetyl neuraminic acid α 2-3 D-galactose β1-3 (*N*-acetyl neuraminic acid α2-6) *N*-acetyl D-galactosaminitol and *N*-acetyl neuraminic acid α2-3 D-galactose β1-3 *N*-acetyl D-galactosaminitol prepared from glycophorin A of human red cells.[19] *N*-acetyl neuraminic acid α2-6 D-*N*-acetyl galactosaminitol was prepared from bovine submaxillary mucin, and ^3H-*N*-acetyl galactosaminitol was made from *N*-acetyl D-galactosamine (Sigma) by reduction with NaB^3H_4.

Assay of UDP-D-galactose: N-*acetyl D-galactosamine β-D-galactosyl transferase activity.* Assay for galactosyl transferase activity was essentially performed according to Cartron et al.[5] Lymphoblastoid cell samples containing 1 mg of protein were solubilized in 130 μL 1% Triton X-100 in PBS at 0 °C. After centrifugation at 10,000 g for ten minutes, the supernatants were recovered. The assay mixture contained 80 μL of cell extract, 40 μL of 0.1 mol/L sodium cacodylate buffer pH 7.0, 20 μL of 0.1 mol/L $MnCl_2\,4H_2O$, 33 μL of 15.1 mmol/L naphtol α-*N*-acetyl D-galactosamine (Koch-Light), 0.25 μCi of UDP-^{14}C-D-galactose (Amersham), and 10 μL of 5% Triton X-100. The samples were incubated at 37 °C, and aliquots were removed at times indicated. The analysis was performed by means of descending chromatography in ethylacetate–pyridine–H_2O (10:4:3) on Whatman 1-mm paper for 12 hours. After being dried, the paper strips were cut into 1-cm pieces and counted for radioactivity in the Triton X-114-band scintillation fluid. The $Rf_{glucose}$ of galactose β1-3 *N*-acetylgalactosamine-α-*p*-nitrophenol was 2:1.

RESULTS

Establishment and general characteristics of T_n-positive and T_n-negative lymphoblastoid cell lines. Epstein-Barr virus infection of blood mononuclear cells results in polyclonal activation and immortalization of B lymphocytes. The lymphoblastoid cell line established from the T_n-positive individual contained ~40% of cells reactive with Hp. The Hp+ and Hp− cells were cloned into sublines by use of the FACS IV after being stained with FITC-conjugated Hp. The Hp+ and Hp− sublines have retained their original phenotypes as regards to lectin reactivities after cultivation for more than one year. Figure 1A shows Hp fluorescence of the unfractionated cells, Fig 1C shows the Hp− cells and Fig 1E

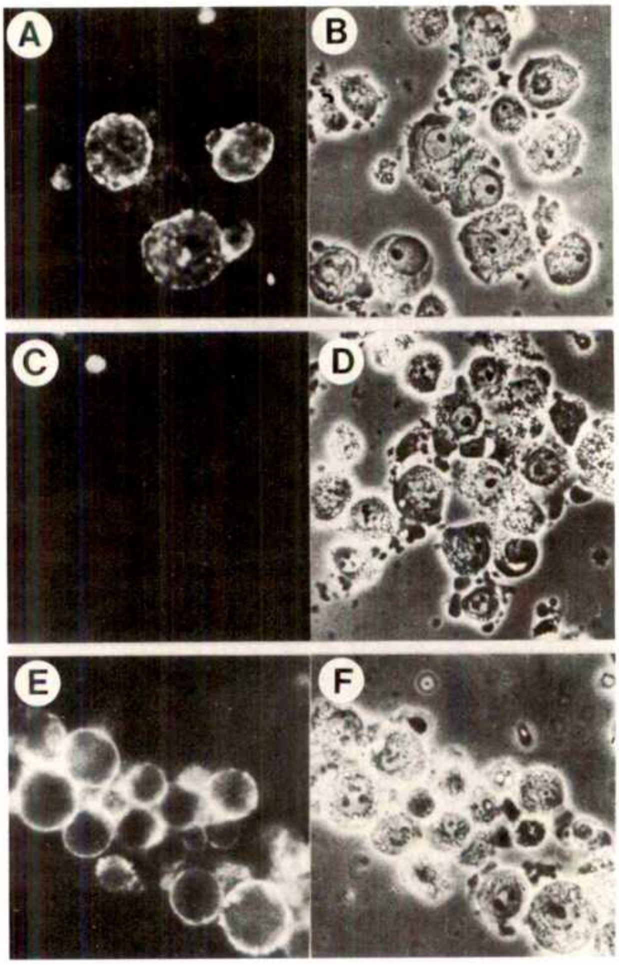

Fig 1. Visualization of *Helix pomatia* lectin positive and negative (Hp+ and Hp−) lymphoblastoid cells by immunofluorescence. The cells to the left are stained with fluorescent Hp, whereas those to the right are visualized by phase contrast illumination. (A and B) Unfractionated lymphoblastoid cells from the T_n-positive individual; (C and D) Hp− cell line; (E and F) Hp+ cell line.

shows the Hp+ cells. Fluorescence was seen only in the Hp+ subline. Both the Hp+ and Hp− cells grow in aggregates characteristic of B lymphoblastoid cells. No differences have been observed in their growth characteristics.

Polyacrylamide gel electrophoresis patterns of galactose oxidase/NaB^{3}H$_4$-labeled cells. Figure 2 shows a polyacrylamide gel of surface-labeled Hp+ and Hp− cells. After treatment with neuraminidase plus galactose oxidase followed by reduction with NaB^{3}H$_4$, the patterns of both cell lines looked similar (Fig 2 B and D). The GP160 through GP200 bands represent the common leukocyte antigen; the GP120 band represents the major O-glycosidic sialoglycoprotein. If the cells were oxidized with galactose oxidase without prior neuraminidase treatment, the patterns were distinctly different. Both the Hp+ and Hp− cells contained label in the common leukocyte antigen bands and in a GP250 glycoprotein, but the GP105 protein was strongly labeled only in Hp+ cells (Fig 2C).

Affinity chromatography of periodate/NaB^{3}H$_4$-labeled cell glycoproteins and their characterization. Detergent-soluble extracts from Hp+, Hp−, and normal periodate/NaB^{3}H$_4$-labeled cells were analyzed on Hp-Sepharose columns (Fig 3). Substantially more radioactivity was retained and eluted from Hp+ cells (Fig 3A), than from Hp− (Fig 3B) or normal lymphoblastoid cells (Fig 3C). Polyacrylamide gel electrophoretic analysis of the Hp+ and Hp− cell extracts chromatographed on Hp-Sepharose columns showed that the GP105 and a diffuse band just below it were the major glycoproteins eluted from Hp+ cells (Fig 4C). The GP160 band was also enriched in the eluate from Hp+ cells, whereas the GP250 glycoprotein was recovered from both cell extracts (Fig 4C and F).

The sugar-eluted peaks from the Hp-affinity chromatographies were subjected to Pronase and alkaline borohydride treatments to liberate glycopeptides/oligosaccharides. The labeled samples were then analyzed by gel filtration on Biogel P-6 columns (Fig 5).

The Hp+ cell glycoproteins contained both *N*-glycosidic and O-glycosidic oligosaccharides (Fig 5A). The complex-type of *N*-glycosidic oligosaccharides elute near the void volume (peak 1). Peak 2 contains O-glycosidic oligosaccharides, which elute in a position similar to that of the major O-glycosidic tetrasaccharide of glycophorin A from red cells.[20] Peak 3 corresponds to the position of *N*-acetyl neuraminic acid α 2–6 *N*-acetyl D-galactosaminitol. When the samples were treated with Pronase only, all radioactivity eluted at the void volume. As was expected, the Hp− and the normal lymphoblastoid cell extracts contained only small amounts of Hp-bound and sugar-eluted glycopeptide/oligosaccharide material (Fig 5 B and C).

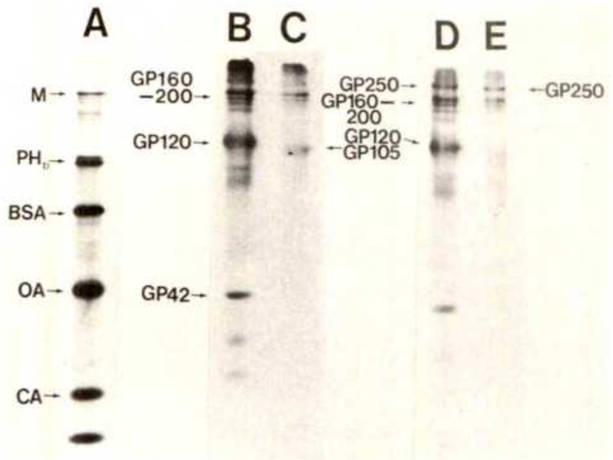

Fig 2. Polyacrylamide slab gel electrophoresis pattern of galactose oxidase/NaB^{3}H$_4$-labeled cells. (A) pattern of ^{14}C-labeled standard proteins. M, myosin; PH$_b$, phosphorylase b; BSA, bovine serum albumin; OA, ovalbumin; CA, carbonic anhydrase. (B) Surface glycoproteins of *Helix pomatia* lectin-positive (Hp+) cells labeled by treatment with neuraminidase and galactose oxidase/NaB^{3}H$_4$. GP160 through GP200, surface glycoproteins with apparent mol wt of 160,000 to 200,000, etc. (C) Surface glycoproteins of Hp+ cells labeled by galactose oxidase/NaB^{3}H$_4$. (D) Surface glycoproteins of Hp− cells labeled by treatment with neuraminidase + galactose oxidase/NaB^{3}H$_4$. (E) Surface glycoproteins of Hp− cells labeled by galactose oxidase/NaB^{3}H$_4$.

Immune precipitation and analysis of the major radioactively surface-labeled glycoproteins. Cell surface labeling by galactose oxidase/NaB^{3}H$_4$ showed label mainly in the GP160–200 and GP105 proteins in Hp+ cells. These proteins were isolated by immune precipitation (Fig 6). The L10 antibody reacted with the labeled GP105 protein from Hp+ cells (Fig 6B), but only a weakly labeled diffuse band with higher apparent mol wt was seen in Hp− cells (Fig 6E). The monoclonal antibody against the common leukocyte antigen reacted well with labeled proteins from both Hp+ and Hp− cells. The precipitated glycoproteins from Hp+ cells had apparent mol wt of 180,000 to 200,000 (Fig 6C), whereas

Fig 3. Affinity chromatography patterns of periodate/NaB^{3}H$_4$-labeled lymphoblastoid cell surface glycoproteins. (A) Pattern obtained with Hp+ cells. (B) Pattern obtained with Hp− cells. (C) Pattern obtained with lymphoblastoid cells originating from a normal individual. Aliquots were counted for radioactivity (25 µl/2 mL). Arrows mark the addition of N-acetyl galactosamine-containing buffer.

(A) Pattern of periodate/NaB^{3}H$_4$-labeled Hp+ cells. (B) Pattern obtained of the unbound glycoproteins from Hp+ cells. (C) Pattern obtained of the lectin-bound and eluted glycoproteins from Hp+ cells. (D) Pattern of periodate/NaB^{3}H$_4$-labeled Hp− cells. (E) Pattern obtained of the unbound glycoproteins from Hp− cells. (F) Pattern obtained of the lectin-bound and eluted glycoproteins from Hp− cells. Apparent mol wt of some major glycoproteins is indicated.

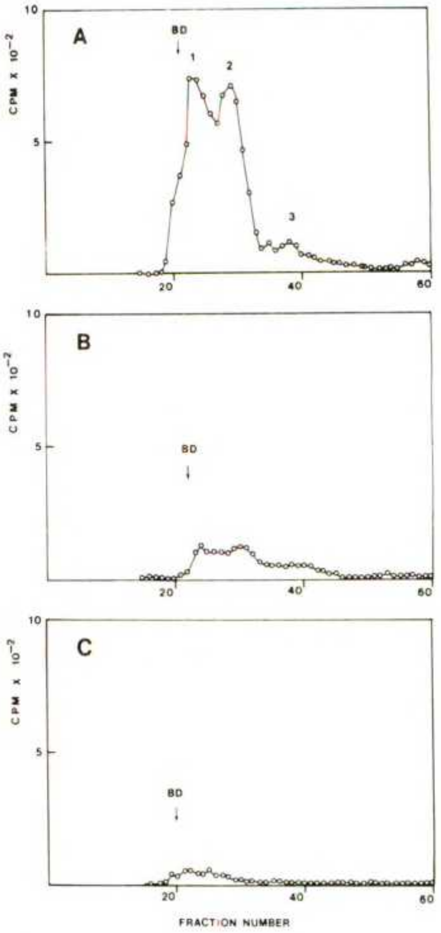

Fig 5. Biogel P-6 gel filtration patterns of *Helix pomatia* lectin (Hp)-Sepharose sugar-eluted fractions treated with Pronase and alkaline borohydride. Similar amounts of periodate/NaB^{3}H$_4$-labeled cells were used for the experiments. (A) Pattern obtained with Hp+ cells. (B) Pattern obtained with Hp− cells. (C) Pattern obtained with lymphoblastoid cells originating from a normal individual. BD, position of Blue dextran. Peak 1 corresponds to the elution volume of *N*-glycosidic complex-type glycopeptides, peak 2 corresponds to the elution position of *O*-glycosidic tetrasaccharides, and peak 3 corresponds to *N*-acetyl neuraminic acid 2-6 *N*-acetylgalactosaminitol.

that from Hp− cells had an apparent mol wt of 160,000 (Fig 6F).

The galactose oxidase/NaB^{3}H$_4$-labeled glycoproteins obtained with the L10 antibody were digested with Pronase and subjected to alkaline borohydride treatment. Gel filtration showed one major peak from the Hp+ GP105 protein, which eluted in the position of N-acetyl galactosaminitol. No peak was obtained from Hp− cells.

The GP105 proteins were also isolated from periodate/NaB^{3}H$_4$-labeled Hp+ and Hp− cells by immune precipitation with the L10 antibody. Biogel P-6 gel filtration showed the presence of complex N- and O-glycosidic glycopeptides/oligosaccharides in both Hp+ cells (results not shown).

UDP-D-galactose N-*acetyl D-galactosamine β-D-galactosyl transferase activities in Hp− and Hp+ cells.* The Hp− cells showed high O-glycosidic galactosyl transferase activity, whereas the activity in Hp+ cells was only 10% to 12% of that (Fig 7).

DISCUSSION

A major unsolved problem in cell biology is the general function(s) of cell surface carbohydrate.[21] The large amount of sugar transferases and processing enzymes needed to build up the diverse carbohydrate chains point to essential roles for these structures. Oligosaccharides are already known to be important in some cases of intercellular adhesion,[22,23] ligand binding,[24,25] in the intracellular transport of newly synthesized glycoproteins,[26,27] and in sorting of lysosomal enzymes.[28-30]

One way of studying functions of carbohydrate groups is to inhibit their synthesis and addition to polypeptides. Several compounds are known to interfere with the synthesis of *N*-glycosidic oligosaccharides. These include tunicamycin, which inhibits the formation of the lipid intermediates,[31] and the different agents which affect the processing of the N-glycosidic oligosaccharides.[32] In some cases, the alterations of cell surface carbohydrates markedly affect the biosynthesis, location, and function of the glycoproteins. No inhibitors or modifiers of the synthesis of O-glycosidic oligosaccharides have been found, however.

Another approach is to use cellular mutants defective in glycosylation. Several such cell lines are available,[3,33] and they have been useful for the elucidation of *N*-glycosidic oligosaccharide processing,[34] and of intracellular glycoprotein transfer routes.[35,36] All described mutants with one exception are specifically affected in *N*-glycosylation. Using the *Vicia villosa* lectin, Conzelmann and Kornfeld recently described a murine cytotoxic T cell mutant lacking terminal β-D-*N*-acetyl galactosamine residues in O-glycosidic oligosac-

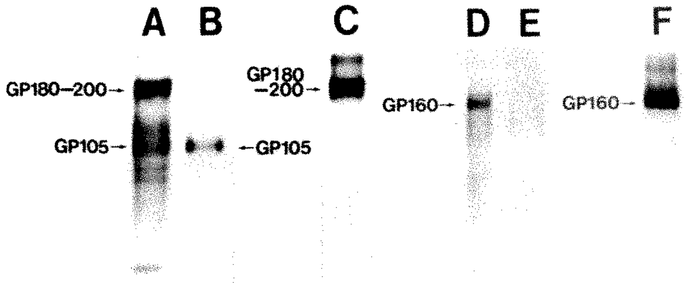

Fig 6. Polyacrylamide gel electrophoresis patterns of immunoprecipitates from *Helix pomatia* lectin positive and negative (Hp+ and Hp−) cells labeled by the galactose oxidase/NaB^{3}H$_4$ technique. (A) Pattern of ^{3}H-labeled Hp+ cells. (B) Pattern obtained with L10 monoclonal antibody from Hp+ cells. (C) Pattern obtained with monoclonal antibody against common leukocyte antigen from Hp+ cells. (D) Pattern of ^{3}H-labeled Hp− cells. (E) Pattern obtained with L10 antibody from Hp− cells. (F) Pattern obtained with monoclonal antibody against common leukocyte antigen from Hp− cells.

charides,[37] which is due to absence of UDP-*N*-acetylgalactosamine: galactose 1,4-*N*-acetylgalactosaminyl transferase.[38] This oligosaccharide structure is evidently uncommon and is probably located on the major sialoglycoprotein of cytotoxic murine T lymphocytes.[39,40]

The receptor for low-density lipoprotein is well characterized. It is highly O-glycosylated.[41] Different functionally defective mutants of this receptor have been described, some of which may be caused by altered O-glycosylation.[42]

Red blood cells of the T$_n$ blood group are polyagglutinable by normal human sera, due to the exposure of terminal *N*-acetyl galactosamine residues in a certain proportion of the red cells which react with naturally occurring antibodies. The molecular defect is known to be due to a decrease or absence of UDP-D-galactose: *N*-acetyl D-galactosamine β-D galactosyl transferase,[5,6] a key enzyme in the biosynthesis of O-glycosidic oligosaccharides.

A comparison between the Hp+ and Hp− lymphoblastoid cells described here shows that the Hp+ cells had only 10% to 12% of the O-glycosidic galactosyl transferase activity of the Hp− cells. This activity may be due to some contaminating Hp− cells. The labeling studies of Hp+ cells using neuraminidase-galactose oxidase/NaB^{3}H$_4$ or periodate/NaB^{3}H$_4$ clearly showed that several surface glycoproteins contained penultimate galactosyl/*N*-acetyl galactosaminyl residues and sialic acids, indicating that there is no large change in *N*-glycosylation.

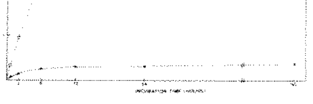

Fig 7. UDP-galactose: *N*-acetylgalactosamine β-galactosyl transferase activity in *Helix pomatia* lectin positive and negative (Hp+ and HP−) cells. The galactosyl transferase activities were measured as described in the Materials and Methods section. The samples were incubated at 37 °C for the times indicated; (O——O) Hp− cells; (x——x) Hp+ cells.

The Hp+ cells contained terminal *N*-acetyl galactosamine residues in the major surface-labeled sialoglycoprotein GP105, which was responsible for the binding to Hp. This sialoglycoprotein and its other leukocyte counterparts[43] are in some respects similar to the major O-glycosidic sialoglycoprotein of red cells, glycophorin A. When glycophorin A was treated with neuraminidase under nondenaturing conditions, its apparent mol wt increased, due to removal of peripheral galactose-linked sialic acids.[19] Similarly, the apparent mol wt of the major leukocyte sialoglycoprotein decreased after neuraminidase treatment (Fig 2).[44,45] The GP105 glycoprotein is probably functionally important. Its T lymphocyte equivalent GP115, reactive with the L10 monoclonal antibody, is either reduced in quantity or absent from lymphocytes of patients with the Wiscott-Aldrich syndrome.[15] These patients suffer from severe immune deficiency.

The GP105 glycoprotein contained O-glycosidic oligosaccharides both in Hp+ and Hp− cells. Although the structure of the larger oligosaccharides is not known, some of them may contain the core structure *N*-acetyl glucosamine β 1–3 *N*-acetyl galactosamine, which has been found in O-glycosidic oligosaccharides.[46,47] In this way, the biosynthesis block caused by the absence of galactosyl transferase could be bypassed.

The common leukocyte antigen is a surface glycoprotein complex showing differing apparent mol wt in T and B lymphocytes.[48-51] These differences have been presumed to be due to varying degrees of glycosylation, but differences in the polypeptide portions have not been ruled out. The observed differences between the common leukocyte antigens of Hp+ and Hp− cells must be due to differences in glycosylation, resulting in changes in apparent mol wt.

It is obviously important to have both "normal" and T$_n$-positive cell lines from the same individual. The cells are useful for studies on the role of O-glycosidic oligosaccharides in the biosynthesis of the GP105 protein and possibly of viral glycoproteins containing O-glycosidic carbohydrate that use the host cell systems for their glycosylation.[52] Until now, few studies have been done on the biosynthesis and O-glycosylation of membrane proteins. Only glycophorin A has been studied in some detail, and its biosynthesis has already revealed a remarkably complex series of events.[53]

ACKNOWLEDGMENT

The skillful technical assistance of Ulla Katajarinne, Marjukka Vaalle, and Helena Nousiainen is gratefully acknowledged. We thank Barbara Björnberg for typing the manuscript and Eileen Remold-O'Donnell, PhD for the L10 antibody.

In Vivo Induction of Terminal Differentiation of Malignant Myelopoietic Progenitor Cells by CSF-Inducing Biological Response Modifiers

By Erich Schlick and Francis W. Ruscetti

We have investigated the mechanisms by which colony-stimulating factor (CSF)–inducing biological response modifiers (BRM) may have beneficial effects on tumor-bearing hosts undergoing anti-tumor therapy. First, we have documented that treatment of mice with the chemically defined BRM maleic anhydride divinyl ether copolymer (MVE-2), which induces CSF secretion by macrophages (Mϕ) and bone marrow cells (BMC), significantly increased growth and differentiation of normal myelopoietic cells and counteracted the myelosuppressive effects of cyclophosphamide (CY). Second, we established that MVE-2 may exert CSF-mediated antitumor effects on certain leukemic tumor cells. Serum from mice pretreated in vivo with MVE-2, which contained CSF, induced terminal differentiation of cloned tumor cells from the CSF responsive WEHI-3B D$^+$ subline in vitro, but not from the WEHI-3B D$^-$ subline, which is unresponsive to CSF. In vivo experiments showed that treatment of mice bearing the WEHI-3B D$^+$ tumor first with CY and three days later with the CSF inducer MVE-2, significantly increased their survival time and rendered 20% to 50% of the tumor-bearing mice disease free. No such effects were obtained in mice bearing the WEHI-3B D$^-$ tumor. Thus, the induction of CSF or other differentiation factors by some BRMs may result in thereapeutic effects against certain leukemias based on at least two distinct mechanisms: In addition to their restorative effects on normal bone marrow functions, CSF-inducing BRMs may also prevent further leukemogenesis by induction of terminal differentiation of leukemic cells.

SEVERAL reports indicate that some immunotherapeutic agents can stimulate in vivo normal myelopoiesis, presumably mediated by CSFs,[1,2] in addition to having an immunomodulating effect on Mϕ and natural killer (NK)–cell activities.[3,4] Since major treatment modalities for various cancers include chemotherapy and/or radiotherapy, which often result in severe suppression of hematopoiesis and immune functions,[5,6] treatment with selected biologic response modifiers (BRMs) might be advantageous to the tumor-bearing host undergoing cytoreductive tumor therapy, (1) by augmenting the host's natural immunity (Mϕ and/or NK cytotoxicity) against tumor cells, (2) by restoring the host's suppressed hematopoietic functions, and (3) possibly by inducing terminal differentiation of certain leukemic tumor cells.

Studies of several murine myeloid leukemia cell lines, especially of the WEHI-3B myelomonocytic leukemia, have shown that these undifferentiated tumor cells could be induced in vitro to differentiate into macrophages (Mϕ) and/or granulocytes, which then exhibit properties similar to those of their normal counterparts.[7,8] Exposure to a variety of chemical agents is able to induce such differentiation in these myeloid leukemia cell lines,[9,10] but analogous differentiation could also be induced by biologic materials, such as postendotoxin serum[11,12] and certain conditioned media.[12,13] Biochemical analysis of these biologic materials indicate that physiologic regulatory molecules such as colony-stimulating factors (CSF), which control in vitro growth and differentiation of normal granulocytes and/or Mϕ, can induce terminal differentiation of myelomonocytic leukemias.[8,12] Of special interest have been the findings that only two out of three different subclasses of CSF are able to induce terminal differentiation. G-CSF, controlling normal granulocyte formation, exhibited high differentiation-inducing activity.[7,13] GM-CSF, controlling normal granulocyte and Mϕ formation, was found to have only weak differentiation-inducing activity, whereas M-CSF, controlling normal Mϕ formation, had no detectable effect on differentiation.[8,14] Since previous studies have indicated that MVE-2 (maleic anhydride divinyl ether copolymer), a chemically defined BRM, might induce increased in vivo secretion of CSFs by Mϕ and BMC[2], in addition to activating Mϕ and NK-cell cytotoxicities[3], we were therefore interested in testing the ability of MVE-2 to modulate (1) the host's myeloid progenitor and immune functions in vivo before and after antineoplastic treatment with cyclophosphamide (CY) and (2) to define the potential of MVE-2 for differentiation of WEHI-3B leukemic cells.

MATERIALS AND METHODS

Male BALB/c mice were obtained from the Mammalian Genetics and Animal Production Section, Division of Cancer Treatment, NCI-FCRF, NIH, Frederick, Md The animals were 6 to 8 weeks of age before they were used for experiments.

Maleic anhydride divinyl ether copolymer (MVE-2) was the generous gift of Dr R. Corrano (Adria Laboratories, Columbus, OH). Lipopolysaccharide from *S. typhimurium* (LPS) was purchased from Difco Laboratories (Detroit, Mich). The alkylating agent cyclophosphamide (CY) was obtained from Sigma Chemical (St. Louis) The media and BRM preparations were tested for endotoxin contamination with the Limulus lysate assay and found to contain less than 0.125 ng/mL.

Tumor cells. WEHI-3B leukemia cells were originally obtained from mineral oil–injected BALB/c mice in 1968 [15] This leukemic cell line grows in liquid culture as a population of undifferentiated blast cells and promyelocytes. The leukemic cells form large colonies in agar medium that are composed of similar cells. Their plating efficiency varies from 30% to 70% [14] The WEHI-3B D$^+$ and WEHI-3B D$^-$ sublines were a generous gift from Dr Peter Ralph, Sloan-Kettering Institute, New York Cells of the WEHL-3B D$^+$ subline are responsive to induction of differentiation, whereas cells of the WEHI-3B D$^-$ subline are unresponsive to the induction of differentiation.[16,17] The present studies were performed using

WEHI-3B D$^+$ and D$^-$ cells grown in liquid suspension culture in RPMI medium with 10% FCS and containing 0.5–2.0 × 10^6 cells/mL. Both cell lines have a doubling time of about 20 hours in vitro and of about 24 hours in vivo. WEHI-3B D$^+$ and D$^-$ cells are equally sensitive to the in vitro cytoreductive effects of an active metabolite of CY, 4-sulfoethylthiocyclophosphamide [4-SET-CY; Asta Z7557][18,19] (donated by Dr P. Hilgard from Asta Werke, Bielefeld, West Germany). The respective ED_{50} (concentration inducing 50% of the maximal effect) for 4-SET-CY-induced growth inhibition were 3 9 μg/mL (WEHI-3B D$^-$ cells) and 5.0 μg/mL (WEHI-3B D$^+$ cells) for a 1 hour incubation with 4-SET-CY (data not shown).

Agar cultures of WEHI-3B D$^+$ and D$^-$ cells were prepared using cloned cells grown in suspension culture in complete RPMI medium [RPMI 1640, supplemented with 10% heat-inactivated fetal calf serum (Gibco, Grand Island, NY), 292 μg/mL L-glutamine (Gibco) and 100 μg/mL gentamycin (Sigma)]. All semisolid agar cultures were prepared as 1 mL cultures in 35 mm Petri dishes using an equal volume mixture of double strength Dulbecco's modified Eagle's medium and 0.6% agar, supplemented with 20% FCS, 292 μg/mL L-glutamine (Gibco), and 100 μg/mL gentamycin (Sigma). The WEHI-3B cells were added to the liquid agar medium and 1 mL volumes containing 300 cells were pipetted into each culture dish containing 0.1 mL of serially diluted serum from mice pretreated 3 hours before with 5 μg/mouse of LPS (postendotoxin serum)[11,12] or 0.1 mL of serially diluted sera from MVE-2–treated mice Serially diluted conditioned media (CM) from macrophages (Mϕ) or bone marrow cells (BMC) from MVE-2–treated mice were tested likewise. The cultures were allowed to gel and then incubated for 7 days at 37 °C and 8% CO_2 in a fully humidified atmosphere. Colonies (>50 cells) were counted after 7 days of incubation and were classified after Wright staining in situ as undifferentiated if they consisted of a tight aggregate of cells with no outlying cells.[7,14] Differentiated colonies were composed of loosely dispersed differentiating granulocytes/Mϕ around a central aggregate.[7,14] Cells were terminally differentiated, when they failed to form new tumor colonies after being replated in subsequent agar cultures without addition of growth and/or differentiation factors.

Macrophages. Resident peritoneal macrophages (Mϕ) harvested by peritoneal lavage, were seeded into 16 mm wells (Costar, Cambridge, Mass) in 1 mL of complete medium. The cultures were incubated for 2 hours and the adherent Mϕ-monolayers (>95% Mϕ as determined by esterase and Wright staining) were washed twice before testing in experiments. The assay for measuring the macrophage-mediated cytotoxicity has been previously described.[20] Briefly, to measure in vivo activation, monolayers of 8 × 10^5 peritoneal Mϕ, harvested at different times after in vivo treatment of the mice with MVE-2, were overlaid with 8 × 10^4 MBL-2 tumor cells in complete medium and 10 ng/mL of LPS were added. All cultures were incubated for an additional 48 hours at 37 °C and 5% CO_2 and viable MBL-2 cells were then determined by trypan blue dye exclusion. The percent inhibition of MBL-2 cell growth due to Mϕ activation was calculated by:

$$\%\ \text{inhibition} = 1 - \frac{\text{mean of MBL cells from drug treated M}\phi}{\text{mean of MBL-2 cells from nontreated M}\phi} \times 100$$

Bone marrow cells. Sterile single-cell suspensions from femoral bone marrow were prepared as previously described.[21] The number of viable nucleated cells in the femur of each mouse was counted in a hemocytometer. To determine the number of granulocyte-Mϕ committed stem cells (GM-CFU-C), a previously described in vitro soft agar culture technique was used.[22] Briefly, 10^5 unfractionated bone marrow cells (BMC) were suspended in 2 mL of 0.3% agar, supplemented with 15% horse serum (Gibco), 15% fetal calf serum (Gibco), and 100 μg/mL of gentamycin/mL (Sigma), and were plated in 35 mm Petri dishes (Falcon, Oxnard, Calif). As CSF source, 0.2 mL supernatant from WEHI-3B cells[17] was used. The cultures were incubated at 37 °C in a fully humidified atmosphere of 7% CO_2 in air. Colonies (>40 cells) were scored and classified on the basis of their morphology at days 7 and 10 of the culture period.

CSF assay. Cell-free supernatants from in vitro- or in vivo-activated Mϕ and mononuclear BMC were harvested after 48 hours of subsequent in vitro culture (37 °C and 5% CO_2) at a cell density of 10^6 Mϕ/mL or 10^7 BMC/mL and kept at −20 °C until assayed CSF concentrations were then determined using a bioassay as previously described.[22,23] Briefly, serial dilutions of the supernatants or sera to be tested for CSF were added to each 35 mm Petri dish containing 10^5 nonadherent BMC from normal mice in 2 mL of 0.3% agar, supplemented with 15% horse serum, 15% fetal calf serum, and 100 μg/mL gentamycin. At the end of the culture period (10 days at 37 °C and 7% CO_2), the colonies (>40 cells) were counted and classified on the basis of their morphology. No colony formation was noted in the absence of either the standard CSF (supernatant from the WEHI-3B cell line), a supernatant from Mϕ or bone marrow cells, or serum. CSF activity is expressed as U/mL.[23,24] The Student's *t* test was used for statistical analysis.

RESULTS

The results of the experiments on the effects of in vivo treatment with MVE-2 on CSF secretion and myeloid progenitor cells in normal and CY-pretreated mice are summarized in Table 1. MVE-2 at a dose of 25 mg/kg induced an increase in CSF secretion by BMC and Mϕ and in serum CSF levels which was followed by significant augmentation in granulocyte-Mϕ progenitor cells and in nucleated BMC per femur (Table 1, group 2 *v* 1 and Fig 1). Optimal effects could be found 3 days after treatment with MVE-2 at 25 mg/kg and lower or higher doses of MVE-2 were less effective.[2] MVE-2, when given 3 days after the bone marrow suppressive agent CY (150 mg/kg),[5] also induced increased secretion of CSF by Mϕ and BMC, stimulated growth and differentiation of myelomonocytic progenitor cells, and thus restored CY-caused myelosuppression (Table 1, group 6 *v* 5). MVE-2, given 1 day after CY, however, failed to enhance CSF secretion by either Mϕ or BMC, or to counteract the myelosuppressive effects of CY (Table 1, group 4 *v* 3).

Sera from MVE-2–treated mice induce differentiation in WEHI-3B D$^+$ leukemia cells. Next, we investigated whether MVE-2–induced CSF would cause in vitro differentiation of WEHI-3B D$^+$ cells, as compared to WEHI-3B D$^-$ cells. Incubation of WEHI-3B D$^+$ cells in agar cultures with sera derived from MVE-2–treated mice (14 hours after injection) caused a significant increase in differentiation into granulocytes/Mϕ of the leukemia cells (up to a serum dilution of 1/64) as compared to sera from PBS-treated animals (Table 2). The differentiation induced in these WEHI-3B D$^+$ cells was in about two thirds of the cases terminal as shown by the failure of these differentiated cells to form new tumor colonies when replated in subsequent agar cultures without any growth and/or differentiation factors (data not shown). Sera from MVE-2–treated mice (harvested 14 hours after injection) also significantly inhibited (up to a serum dilution of 1/32) the growth of WEHI-3B D$^+$ cells in liquid suspension cultures (Fig 2). The effects of sera from mice harvested at different times after treatment with

‖$P < 0.01$ as compared to group 5

MVE-2 on terminal differentiation of WEHI-3B D$^+$ cells paralleled their stimulatory effects on normal myelopoiesis at all times (Fig 1). Incubation of WEHI-3B D$^+$ cells in agar or liquid suspension cultures with serial dilutions of conditioned media from Mφ and BMC of MVE-2–treated mice gave similar results with respect to terminal differentiation (Table 3) and growth inhibition (data not shown) as sera from the same animals. The effects of CM from Mφ or BMC harvested at different times after treatment with MVE-2 on terminal differentiation of WEHI-3B D$^+$ cells paralleled their stimulatory effects on normal myelopoiesis at all times (data not shown). Postendotoxin serum served as a positive internal control.[11,12] Cells of the WEHI-3B D$^-$ subline were unresponsive to sera from PBS or MVE-2–treated mice with respect to terminal differentiation (Table 2) or growth inhibition (Fig 2). Conditioned media from BMC or Mφ of MVE-2–treated mice also failed to induce either differentiation (Table 3) or growth inhibition of WEHI-3B D$^-$ cells (data not shown). Likewise, WEHI-3B D$^-$ cells failed to respond to postendotoxin serum (data not shown). Heating of the sera and CM of Mφ and BMC from MVE-2–treated mice (56 °C and 30 min) did not change their stimulatory effect on normal myelopoiesis[2] or their differentiation-inducing activity on WEHI-3B D$^+$ cells (data not shown), suggesting that CSF inhibitors were not present in these sera or CMs. We also incubated WEHI-3B D$^+$ and D$^-$ cells in agar and in liquid suspension cultures directly with MVE-2, at concentrations ranging from 1 to 100 μg/mL to rule out any direct cytotoxic effects of the agent. MVE-2 at these concentrations had no significant growth inhibitory effect and did not induce differentiation of the leukemic cells (data not shown).

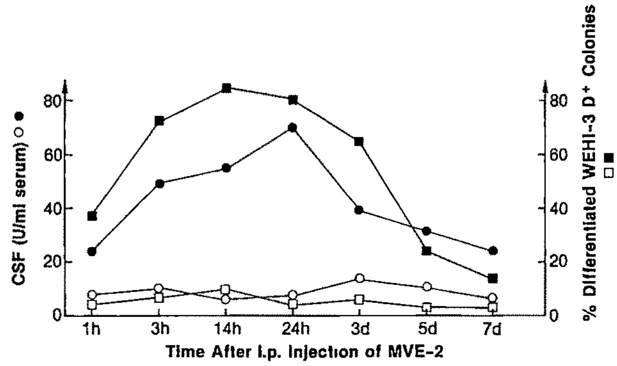

Fig 1. BALB/c mice received a single IP injection of either PBS (open symbols) or 25 mg/kg of MVE-2 (closed symbols). The mice were killed at the times indicated and their sera were harvested for determination of CSF concentrations and for induction of differentiation of WEHI-3B D$^+$ cells. The results are expressed as units of CSF/mL serum or % differentiated WEHI-3B D$^+$ colonies (at a serum dilution of 1/8) and are the mean values of a typical experiment (SD was less than 20%). The experiment was repeated two times and yielded similar results. Incubation of WEHI-3B D$^-$ cells with sera from PBS- or MVE-2–treated mice resulted in up to 5% differentiated WEHI-3B D$^-$ colonies (data not shown).

*Groups of 20 mice were injected IP with either PBS or 25 mg/kg MVE-2. Peritoneal Mϕ and nucleated BMC were collected 14 hours after injection and conditioned media (CM) were prepared by incubating 10^6 Mϕ/mL or 10^7 BMC/mL for 2 days in complete medium without any stimulus.

†300 WEHI-3B leukemia cells were plated in 1 mL 0.3% agar containing Mϕ-CM or BMC-CM at different dilutions. Each value represents the mean percentage of differentiated colonies of duplicate cultures; SD was less than 20% of the mean. The experiment was repeated 2 times with similar results.

‡300 WEHI-3B leukemia cells were plated in 1 mL of 0.3% agar containing 0.1 mL medium.

Combined treatment of WEHI-3B D^+ or D^- tumor-bearing mice with CY and MVE-2. We then wanted to determine whether MVE-2 could be used in vivo, either alone or in combination with CY, for specific treatment of mice bearing WEHI-3B D^+ cells.

Inoculation of BALB/c mice IP with 10^5 WEHI-3B (D^+ or D^-) leukemic cells led to the development of ascitic tumors. The medium survival time (MST) of the tumor controls was about 19 to 20 days with no surviving animals, regardless of the subline inoculated (Figs 3 and 4). Subsequent incubation of WEHI-3B (D^+ + D^-) cells, harvested by peritoneal lavage from the tumor controls 8 days after tumor inoculation in agar cultures, resulted in a 3% to 5% spontaneous differentiation (Table 4).

Treatment of animals bearing the WEHI-3B D^+ subline with MVE-2 (25 mg/kg), 3 and 6 days after tumor inoculation, increased the MST to day 27 (+35% above controls; Fig 3). MVE-2 also induced differentiation in 26% of the remaining peritoneal tumor cells (Table 4). A single IP injection of CY (150 mg/kg) 3 days after tumor inoculation, prolonged the MST to day 28.5 (+ 42% above controls; Fig 3) and induced differentiation in 14% of the remaining peritoneal tumor cells (Table 4). No surviving animals are found after treatment with either MVE-2 or CY alone. Combined treatment with CY (at day +3) and MVE-2 (at day +6), however, delayed MST to day 47.5 (+ 137% above controls), with 30% of the animals still disease free, when the experiment was terminated 90 days after tumor inoculation (Fig 3). The percent survivors after such combined CY/MVE-2 treatment varied in the different experiments between 20% and 50%. The combined CY/MVE-2 treatment also induced differentiation in 61% of the peritoneal tumor cells remaining at day 8 (Table 4).

MVE-2 injections (25 mg/kg) of animals bearing the WEHI-3B D^- subline on days 3 and 6 after tumor inoculation increased the MST of these animals to day 24 (+ 26% above controls), while a single IP injection of CY (150 mg/kg) on day 3 delayed their MST to day 28 (+ 47% above controls; Fig 4). Combined treatment of these mice with CY (at day + 3) and MVE-2 (at day + 6) prolonged MST to day 35, which was an increase of 84% above the MST of the controls (Fig 4). However, neither treatment with MVE-2 or CY alone nor combined treatment with CY/MVE-2 given at a 3-day interval resulted in any surviving animals (Fig 4). Furthermore, none of the treatment regimens used induced differentiation of the peritoneal WEHI-3B D^- tumor cells remaining at day 8 (Table 4).

We then decided to treat tumor-bearing animals with CY/MVE-2 at a one-day time interval (CY at day 3 and MVE-2 at day 4), which does not result in increased CSF levels in vivo (Table 1).

The results in Table 5 show that such a treatment delayed the MST of animals bearing the WEHI-3B D^- or D^+ subline to 32 or 33.5 days, respectively, and no survivors were found. Furthermore, combined treatment with CY on day 3 and

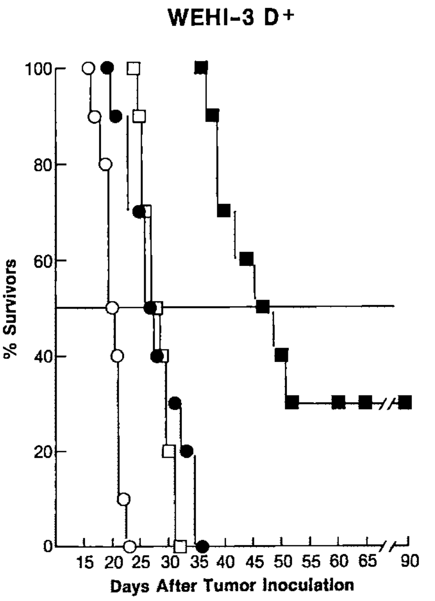

Fig 3. BALB/c mice were inoculated IP with 10⁵ WEHI-3B D⁺ leukemic cells on day 0. Controls (○) were injected IP on day +3 and day +6 with PBS. Some of the mice received eitehr 25 mg/kg of MVE-2 IP on day +3 and day +6 (●) or 150 mg/kg of CY on day +3 (□). Combined treatment with CY (150 mg/kg IP) and MVE-2 (25 mg/kg IP) was administered on day +3 (CY) and day +6 (MVE-2) following tumor inoculaton (■). The mice were monitored for tumor growth, terminal differentiation of tumor cells, and 10 mice/group were kept for median survival time. The results are the mean of a typical experiment, which was repeated 3 times with similar results. The percent of survivors after combined CY/MVE-2 treatment varied in the different experiments between 20% and 50%.

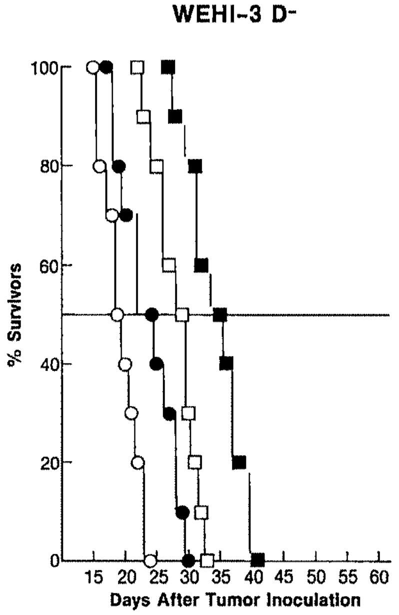

Fig 4. BALB/c mice were inoculated IP with 10⁵ WEHI-3B D⁻ leukemic cells on day 0. Controls (○) were injected IP on day +3 and day +6 with PBS. Some of the mice received either 25 mg/kg of MVE-2 IP on day +3 and +6 (●) or 150 mg/kg of CY on day +3 (□). Combined treatment with CY (150 mg/kg IP) and MVE-2 (25 mg/kg IP) was administered on day +3 (CY) and day +6 (MVE-2) following tumor inoculation (■). The mice were monitored for tumor growth, terminal differentiation of tumor cells, and 10 mice/group were kept for median survival time. The results are the mean of a typical experiment, which was repeated 3 times with similar results.

MVE-2 on day 4 induced a differentiation only in 17% of the peritoneal WEHI-3B D$^+$ cells remaining at day 8, which was not different from the CY control (14%; data not shown). No differentiation was found in the remaining WEHI-3B D$^-$ tumor cells (data not shown).

The residual undifferentiated peritoneal WEHI-3B D$^+$ tumor cells, after treatment with either MVE-2, CY, or CY combined with MVE-2, retained their sensitivity to subsequent in vitro induction of differentiation by postendotoxin serum when tested at day 8, whereas the residual peritoneal WEHI-3B D$^-$ tumor cells remained insensitive to postendotoxin serum with regard to in vitro differentiation or growth inhibition, suggesting these subline are stable (data not shown).

Susceptibility of WEHI-3B D$^+$/D$^-$ leukemic cells to cytotoxicity by Mϕ or NK cells. Since MVE-2 is reported to increase cytotoxicity by Mϕ and NK-cells against various tumor targets[3,4] and treatment with MVE-2 alone or CY combined with MVE-2 was still effective in treating mice bearing the (CSF-insensitive) WEHI-3B D$^-$ subline, we wanted to test whether both tumor sublines were susceptible to cytotoxic Mϕ and/or NK cells.

Both sublines of WEHI-3B (D$^+$/D$^-$) were highly sensitive to Mϕ cytotoxicity at E:T ratios of ≥5:1, whereas they were insensitive to NK-cell cytotoxicity at E:T ratios of ≤200:1 (Table 6). MBL-2 tumor cells were internal positive controls

*BALB/c mice received on day 0 10⁵ WEHI-3B D⁻ or WEHI-3B D⁺ leukemia cells IP Controls were injected IP on day +3 and day +6 with PBS. Mice from group 2 received 25 mg/kg of MVE-2 IP on day +3 and day +6. Mice from group 3 and 4 were injected on day +3 with 150 mg/kg cyclophosphamide and on day +6 with either PBS or 25 mg/kg MVE-2. All mice were killed on day +8. Their peritoneal cavity was lavaged with 10 mL complete medium and the peritoneal fluid, containing peritoneal exudate cells and WEHI-3B leukemia cells, was harvested. The Mϕ were separated by plastic adherence and the nonadherent WEHI-3B cells were used for determination of their differentiation status.

†300 leukemia cells were plated in 1 mL of 0.3% agar without addition of any sera. Each value represents the mean percentage of differentiated colonies of duplicate cultures, initiated from 5 mice per group; SD was less than 25% of the mean. The experiment was repeated two times with comparable results.

Table 5. MST of WEHI-3B Tumor-Bearing Mice After Combined CY/MVE-2–Treatment Given at a One-Day Time Interval

		MST (days)	
Group	Treatment*	WEHI-3B D^- Tumor Cells	WEHI-3B D^+ Tumor Cells
1	Control	20	19
2	CY (150 mg/kg); day 3	28	29
3	CY (150 mg/kg) on day 3 and MVE-2 (25 mg/kg) on day 4	32	33.5

*BALB/c mice received on day 0 10^5 WEHI-3B D^+ or D^- leukemic cells. Controls were injected IP on day +3 and day +4 with PBS. Mice from groups 2 and 3 received 150 mg/kg of CY on day +3 and PBS (group 2) or 25 mg/kg of MVE-2 (group 3) on day +4. The mice were monitored for tumor growth, terminal differentiation of tumor cells, and 10 mice/group were kept for median survival time (MST). The results are the mean of a typical experiment, which was repeated 3 times with similar results

for Mϕ cytotoxicity[20] and YAC-1 tumor cells[25] for NK-cell cytotoxicity (Table 6).

DISCUSSION

The data presented here show that a chemically defined BRM, MVE-2, may induce in vivo terminal differentiation of malignant myelopoietic progenitor cells, in addition to stimulating growth and differentiation of normal myelopoietic progenitors. These effects on normal or malignant myelopoietic cells, however, appear not to be caused directly by MVE-2, but rather to be mediated through CSFs. This is supported by the observation that MVE-2 has no direct stimulatory or inhibitory effects on normal bone marrow cells grown in soft agar with or without addition of CSF.[2,23] Furthermore, MVE-2 failed to directly induce in vitro differentiation and/or growth inhibition of WEHI-3B D^+ cells. On the other hand, sera or supernatants from BMC and Mϕ of mice pretreated in vivo with MVE-2, which contained different CSFs (these data and reference 2), caused differentiation of malignant myelopoietic progenitor cells. A carry over of MVE-2 with serum to our in vitro cultures can be excluded, since pharmacokinetic studies on the distribution of MVE-2 after in vivo treatment showed that MVE-2 has a short serum half-life.[26]

Although the CSF molecules in serum and supernatants of BMC and Mϕ were not purified, the morphology of the bone marrow colonies induced by these fluids seem to point out[27–29] that sera- and BMC-derived supernatants contained three types of CSF, namely M-CSF, GM-CSF, and G-CSF, as evidenced by the findings of pure Mϕ colonies, mixed granulocyte-Mϕ colonies, and pure granulocyte colonies.[2] Mϕ-derived supernatants contained only M-CSF and G-CSF, as evidenced by the outgrowth of pure Mϕ and pure granulocyte colonies.[2]

While it seems to be clear that CSFs are the major regulator of normal myelopoiesis,[30,31] the problem of whether CSFs are also the major physiologic inducer of differentiation in myelomonocytic leukemias, such as WEHI-3B D^+ cells, is not yet solved. There is experimental evidence that, besides CSFs, there exist factor(s), such as MGI-2[32,33] (also referred to as MGI,[34] D. factor,[35] and GM-DF[11]), which seem to induce differentiation of myelomonocytic cells, while supposedly lacking growth regulatory effects on normal myelopoiesis. However, in conflict with this, others have suggested that GM-DF for myeloid leukemic cells might be identical with G-CSF, inducing growth and differentiation of normal and terminal differentiation of malignant myeloid cells [11,13,16] In our experiments, sera, Mϕ, and BMC supernatants of MVE-2–pretreated mice contained the relevant subclasses of CSF (GM-CSF and G-CSF), which have been shown to induce in vitro differentiation of WEHI-3B D^+ cells,[7,13,14] while lacking such effects on WEHI-3B D^- [these data and reference 17]. The fact that these activities on normal and malignant myeloid progenitors of sera and Mϕ/BMC supernatants from MVE-2–pretreated mice, which were free of CSF inhibitors, showed a parallel time course would support the notion that relevant CSFs present in these fluids (GM-CSF and/or G-CSF) caused the terminal differentiation of the WEHI-3B D^+ cells. This does not, however, exclude the possibility of the concomitant presence of a separate differentiating factor.

The observed therapeutic effects after treatment of mice bearing the WEHI-3B D^+ or WEHI-3B D^- subline with CY

*BALB/c mice received on day 0 a single IP injection of either PBS or 25 mg/kg MVE-2. All mice were killed on day +3 for determination of peritoneal Mϕ and spleen NK-cell cytotoxicities against different tumor targets. Each value represents the mean of two separate experiments; SD was less than 20% of the mean.

†Mϕ cytotoxicity of peritoneal Mϕ was determined at different E:T ratios.

‡NK cell cytotoxicity of splenic lymphocytes was determined at different E:T ratios in a 4 hour ^{51}Cr-release assay.[26]

§$P < 0\ 001$ relative to controls

and/or MVE-2 could be due to either one or a combination of the following mechanisms. (1) direct cytotoxic effects of CY on either subline; (2) Mϕ-mediated cytotoxicity on cells of either subline, and (3) CSF-mediated differentiation of the WEHI-3B D$^+$, but not the WEHI-3B D$^-$ subline. Since both sublines have the same origin,[17] are comparable in their biologic behavior (except the induction of differentiation in WEHI-3B D$^+$ cells),[17] and were equally sensitive to Mϕ-mediated cytotoxicity and CY toxicity, the differences in MST between both sublines, treated with MVE-2 alone or a combination of CY and MVE-2, are therefore most likely attributable to CSF-induced differentiation of WEHI-3B D$^+$ cells. This hypothesis is supported by the finding of an increased percentage of differentiated WEHI-3B D$^+$ cells after preceding in vivo therapy with MVE-2 alone or a combination of CY and MVE-2, given at an interval, which allows in vivo induction of CSF.

Treatment of either subline with MVE-2 alone was marginally effective, probably due to the fact that treatment commenced only on day 3, when the IP tumor burden already exceeded 6×10^5 tumor cells (data not shown). We therefore decided to dramatically reduce the tumor burden by CY to a stage of minimal disease before using MVE-2 as Mϕ activator and differentiation-inducing agent. Since our studies have shown that an interval of about 3 days between CY and MVE-2 was optimal for CSF induction and reconstitution of CY-depressed myelopoiesis (these data and reference 36), and regrowth of CY-treated WEHI-3B D$^+$ or D$^-$ cells did not occur until about 4 days after CY (data not shown), we elected a 3-day interval for MVE-2 treatment after preceding high-dose CY. The combined CY/MVE-2 treatment given at a 3-day interval of WEHI-3B D$^-$ tumor-bearing mice significantly increased their MST by about 84% above controls, most likely due to cytoreduction by CY and also more effective Mϕ-mediated cytotoxicity at the minimal residual disease stage (ie, higher Mϕ effector to target cell ratio). The successful treatment, however, of mice bearing the WEHI-3B D$^+$ subline with CY/MVE-2, when given at a 3-day interval (137% increase in MST and 20% to 50% cured mice), seems to be correlated not only with the reduced tumor burden (CY and Mϕ-mediated), but also with the induction of differentiation in remaining tumor cells, which was in a high percentage of the cases terminal, thus preventing further leukemogenesis.[33,37] This is supported by the findings that treatment of mice bearing WEHI-3B tumor cells with a combination of CY and MVE-2, given at a one-day interval, which does not allow the in vivo induction of CSF, resulted only in a rather small increase in MST with no surviving animals; also no differences were found between the WEHI-3B D$^+$ and D$^-$ sublines. Furthermore, MVE-2 given one day after CY failed to induce differentiation in the remaining WEHI-3B D$^+$ cells. The finding that the residual undifferentiated WEHI-3B D$^+$ tumor cells after treatment with CY/MVE-2 remain sensitive to differentiation with CSF seems to rule out the possibility of an immediate in vivo selection process for WEHI-3B D$^-$ variants, which would preclude further cyclic treatment with CY/MVE-2.

Our studies thus show that combined treatment of WEHI-3B D$^+$ tumor-bearing mice with CY and the BRM, MVE-2 depend on an optimal treatment schedule, which takes into account the time course of the cytoreductive effects of CY on the tumor cells, as well as the modification of the host's immune system. Furthermore, MVE-2 offers the distinct advantage of being a potent CSF inducer, which in turn has profound effects on CY-depressed myelopoiesis and terminal differentiation of certain myelomonocytic tumor cells. Even though it is unlikely that the results obtained with the differentiation-inducible murine WEHI-3B D$^+$ leukemia can be extrapolated to the majority of primary murine or human myelomonocytic leukemias, our results and those of others[33,38] clearly indicate that biologic response modification may occur in vivo leading to phenotypic changes of tumor cells, thus possibly eliminating the growth advantage of leukemic tumor cells relative to the normal myelomonocytic stem cell population[39] and/or preventing further leukemogenesis.[33,37]

ACKNOWLEDGMENT

Mechanisms of Adenosine 5'-Monophosphate Catabolism in Human Erythrocytes

By Donald E. Paglia, William N. Valentine, Misae Nakatani, and Richard A. Brockway

Uncertainties regarding the role of pyrimidine nucleotidase (PyrNase) in AMP catabolism were resolved by studies of erythrocytes from normal controls, controls with young mean cell ages, and patients with hereditary hemolytic anemia due to severe deficiency of PyrNase. Hemolysates from the latter exhibited undiminished capacity to dephosphorylate AMP over a broad range of pH, indicating that PyrNase was not directly involved. In each subject group, the rates of AMP dephosphorylation between pH 5.1 and 8.3 were indistinguishable from those of IMP, suggesting a potential role for AMP-deaminase, an erythrocyte enzyme that was stimulated by coformycin at pH 7.2. Quantitative analysis of catabolites in incubated hemolysates confirmed that AMP degradation preferentially occurred via deamination to IMP with subsequent dephosphorylation by another erythrocyte nucleotidase isozyme, deoxyribonucleotidase. Both AMP-deaminase and deoxyribonucleotidase have acidic pH optima with minimal activities at physiologic pH, suggesting that this pathway of AMP catabolism could accelerate depletion of the adenine nucleotide pool and thereby mediate the demise of senescent erythrocytes sequestered in the spleen.

NUCLEOTIDASES (5'-ribonucleotide phosphohydrolase, E.C.3.1.3.5) comprise an enzyme class that is common to microorganisms and to most plant and animal tissues. Individual isozymes dephosphorylate both purine and pyrimidine 5'-monophosphates with variable effectiveness, but human erythrocytes contain an isozyme (pyrimidine nucleotidase, PyrNase) uniquely restricted to pyrimidine substrates.[1,2] Such substrate specificity presumably preserves adenosine 5'-monophosphate (AMP), which is in equilibrium with the di- and triphosphates (ADP, ATP) essential to normal cellular function and longevity.

Under some in vitro circumstances, human hemolysates and partially purified enzyme preparations appear to degrade AMP actively. This has been attributed to PyrNase activity, but may actually represent alternative catabolic pathways. One such possibility, conversion of AMP to inosine 5'-monophosphate (IMP) by AMP-deaminase with subsequent dephosphorylation by another nucleotidase isozyme, deoxyribonucleotidase (dNase), is supported by data in the present study.

MATERIALS AND METHODS

The ability of hemolysates to liberate inorganic phosphate (P_i) from AMP and other purine and pyrimidine 5'-monophosphate substrates was assessed by modification[3] of a technique described previously.[1] Nucleotidase activities as a function of pH were determined on 14 blood samples from 13 normal controls, on samples from nine subjects with reticulocytosis (4% to 23%, mean = 8.5%) but with no identifiable enzyme defect, and on six samples from three subjects with hemolytic anemia secondary to severe (<5%) hereditary deficiency of PyrNase (7% to 12% reticulocytes, mean = 10.5%).

Saline suspensions of washed erythrocytes prepared by internationally standardized techniques[4] were lysed by sonication and dialyzed free of endogenous phosphates against 200 volumes of isotonic saline buffered to pH 8.0 with 10 mmol/L Tris-HCl containing 10 mmol/L $MgCl_2$, 0.02 mmol/L EDTA, and 1 mmol/L mercaptoethanol at 4 °C. Hemolysates were redialyzed against fresh solutions for 2 hours prior to assay. Aliquots of dialyzed hemolysate were incubated at 37 °C in 0.15 mmol/L Tris-maleate buffer with 8.5 mmol/L $MgCl_2$, 0.5 mmol/L dithiothreitol, and 2.3 mmol/L AMP or other substrates. Final pH of each incubation mixture was varied at eight points between pH 5.1 and 8.3 and was measured both before and after the 2-hour incubation period with a Beckman Model pHI 41 digital pH meter calibrated against Beckman standard phosphate buffers. Reactions were terminated by addition of equal volumes of 1.2 N perchloric acid. Inorganic phosphate was measured by the Fiske and SubbaRow technique.[5] Reagent blanks were incubated with hemolysate alone, the appropriate substrate being added after acid deproteinization

To measure AMP or dAMP degradation products directly, dialyzed hemolysate was buffered with either 25 mmol/L Tris-HCl, pH 7.4, or 0.25 mol/L potassium succinate, pH 6.2, containing 8 mmol/L $MgCl_2$, 0.6 mmol/L dithiothreitol, 2.2 mmol/L AMP or dAMP, with or without 0.04 mmol/L coformycin Final pH was 7.2 (Tris-HCl) or 6.2 (succinate).

Reactions were terminated by heating to 100 °C for 10 minutes. Supernates, filtered free of coagulum, were assayed for residual substrate and degradation products by enzymatic techniques.[6,7] Aliquots of deproteinized supernate were buffered with 0.1 mol/L Tris-HCl, pH 8.0, containing 0.5 mmol/L EDTA, 2 mmol/L $MgCl_2$, and 0.05 mmol/L sodium phosphate. Addition of 0.005 mL commercial preparations of xanthine oxidase, nucleoside phosphorylase, 5'-nucleotidase, alkaline phosphatase, and adenosine deaminase in various sequences and combinations allowed measurement of hypoxanthine, inosine/deoxyinosine, IMP/dIMP, and adenosine/deoxyadenosine by monitoring absorbance at 293 nm.[6,7]

For ease of comparison, nucleotidase activities and generation of specific reaction products are expressed in common units (U), micromoles produced per hour per gram of hemoglobin (Hgb). Although these are expressed as reaction rates, they may more closely approximate equilibrium concentrations of metabolites in some prolonged incubations that have high initial reaction rates and consequent substrate depletion.

RESULTS

Regardless of whether subjects were normal controls, controls with reticulocytosis, or patients with severe PyrNase deficiency, their incubated hemolysates generated P_i from AMP and IMP at virtually identical rates. As shown in Fig 1, this occurred throughout the entire pH range studied (pH

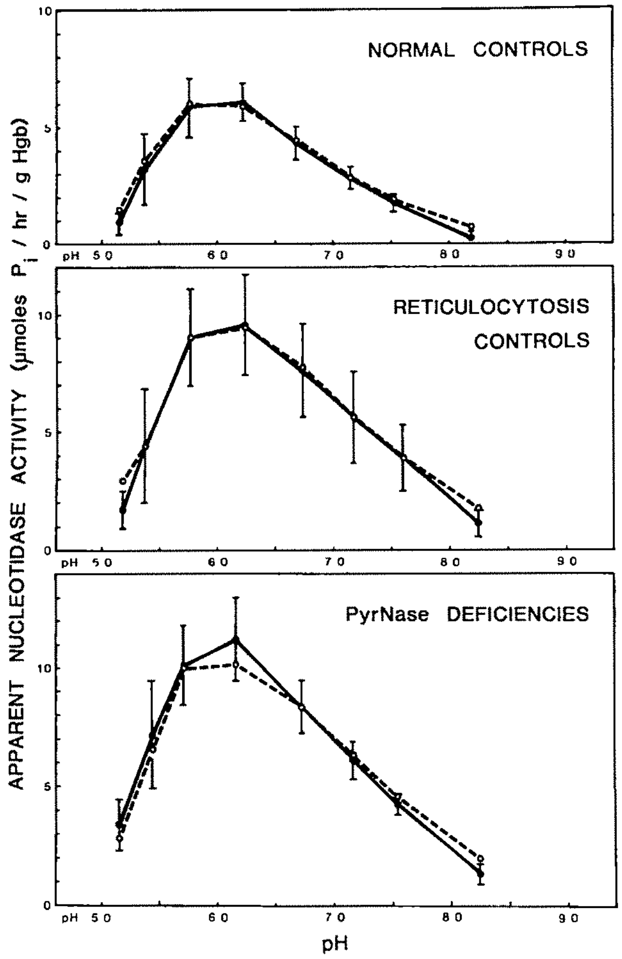

Fig 1. Inorganic phosphorous generation from AMP (solid curves) and IMP (broken curves) as a function of pH. Each point is the mean of multiple assays on 6 to 14 specimens from 3 to 13 subjects as described under Methods. Brackets indicate ±1 SD around mean values for AMP.

5.15–8.25). Subjects with reticulocytosis exhibited predictably greater activities than normal controls, since most enzymes, including PyrNase,[1,2] are more active in young erythrocytes than in older cohorts. There was no apparent difference in P_i production from AMP between subjects with PyrNase deficiency and controls with reticulocytosis, indicating that erythrocyte PyrNase was not the source of AMP dephosphorylation under these conditions.

Similar pH-optima curves for IMP and dIMP, shown in Fig 2, indicate that these nucleotides are also ineffective substrates for PyrNase. Erythrocytes from a patient with severe PyrNase deficiency showed greater activities with IMP and dIMP than did 10 normal controls or 5 to 11 subjects with reticulocytosis (latter values not shown in Fig 2). Similarities in pH optima for IMP and dIMP, coupled with major differences in their relative activities, may be an expression of variable substrate preference (cross-reactivity) of erythrocyte dNase, which is optimally active at pH 6.2.[3]

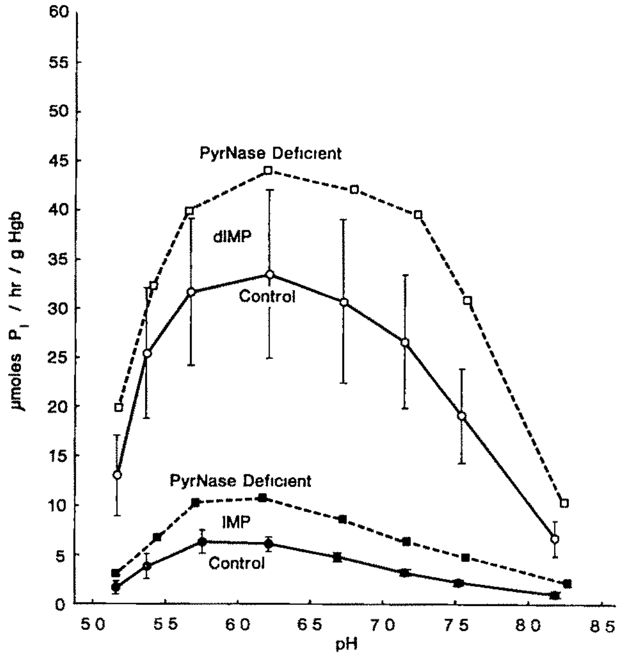

Fig 2. Inorganic phosphate generation from IMP (solid symbols) and dIMP (open symbols) as a function of pH. Each point is the mean of 10 determinations with normal control hemolysates (solid curves) or two assays of duplicate specimens from a single subject with severe hereditary PyrNase deficiency (broken curves). Brackets indicate ± 1 SD around control curves.

Identical rates of P_i production from AMP and IMP over a broad range of pH strongly suggested that erythrocyte AMP-deaminase might convert AMP to IMP prior to dephosphorylation. This hypothesis was supported by in vitro incubation experiments with normal control erythrocytes, which are summarized in Table 1. When hemolysates were incubated at pH 7.2 under conditions commonly used for assay of PyrNase activity, AMP was preferentially converted to IMP (5.8 U) rather than into adenosine (undetectable) and P_i (0.8 U). (The sensitivity of the assay system is such that values in the region of 0.5 U or below are negligible and

*ND = not detectable.

not reliably reproducible). Traces of inosine (0.8 U) and hypoxanthine (0.6 U), if real, may have derived from subsequent degradation of either adenosine (via adenosine deaminase) or IMP (via dNase) (Fig 3). The latter would seem more likely, since inhibition of adenosine deaminase with coformycin did not result in adenosine accumulation (Table 1).

In six paired experiments at pH 7.2, dIMP was not produced in detectable quantities from dAMP, whereas IMP production from AMP was abundant (5.8 to 26.6 U). Other potential dAMP degradation products (deoxyadenosine, deoxyinosine, hypoxanthine, and P_i) were also sparse. This is consistent with the observation that erythrocyte AMP-deaminase cannot utilize dAMP as substrate.[6] At pH 6.2, however, significant quantities of purine degradation products and P_i were generated from dAMP in almost equivalent amounts, consistent with erythrocyte dNase activity, which is optimal at pH 6.2.[3]

As an incidental observation, the presence of coformycin at pH 7.2 increased the yield of IMP from AMP fourfold (Table 1). This was an invariable effect in each of the seven paired hemolysates incubated with AMP. At pH 6.2, similarly high yield of IMP occurred regardless of the presence or absence of coformycin. No comparable differential in dIMP production from dAMP was induced by coformycin at either pH 7.2 or 6.2.

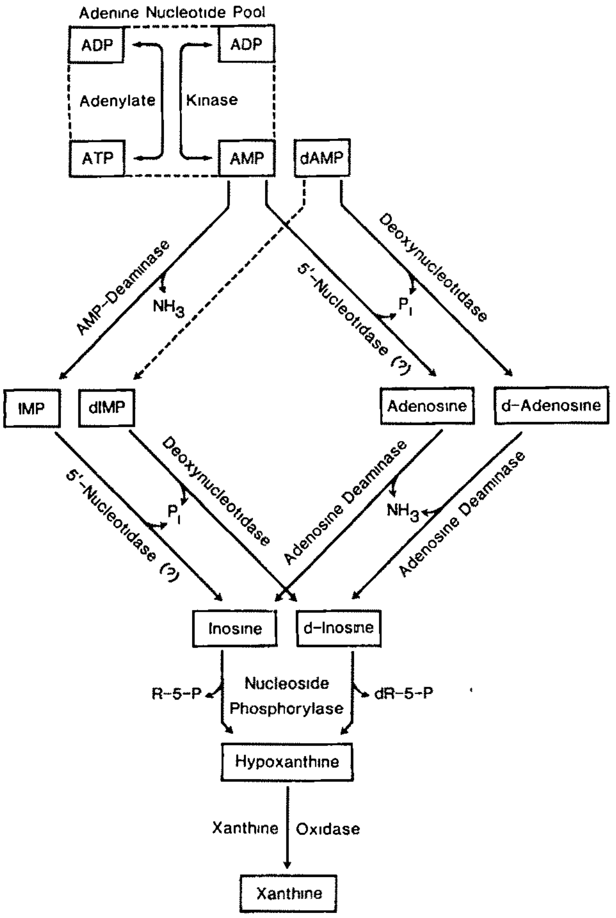

Fig 3. Potential pathways of AMP and dAMP catabolism in human erythrocytes. Erythrocyte AMP-deaminase is inactive with dAMP. Pathways designated "5'-Nucleotidase (?)" are more likely mediated by deoxyribonucleotidase cross-reacting with nondeoxy substrates. Coformycin blocks the adenosine deaminase reaction.

DISCUSSION

Erythrocytes depend on energy stored in terminal phosphate bonds of ATP to fuel a number of metabolic reactions essential to normal function and longevity. Although AMP constitutes only 1% to 3% of the total adenine nucleotide pool, it occupies a pivotal position in the metabolic economy of the cell.

First, it is in rapid equilibrium with the other nucleotide components, mediated by an active adenylate kinase:

$$\mathrm{AMP} + \mathrm{ATP} \underset{\text{Kinase}}{\overset{\text{Adenylate}}{\longleftrightarrow}} 2\,\mathrm{ADP}$$

Second, formation of AMP from plasma adenosine provides an essential salvage pathway for nucleotide replenishment:[8,9]

$$\text{Adenosine} + \mathrm{ATP} \xrightarrow[\text{Kinase}]{\text{Adenosine}} \mathrm{AMP} + \mathrm{ADP}$$

Third, adenine nucleotides, which cannot be synthesized de novo, may be irretrievably lost by conversion of AMP to nonutilizable metabolites, for example, by deamination:

$$\mathrm{AMP} + \mathrm{H_2O} \xrightarrow{\text{AMP-Deaminase}} \mathrm{IMP} + \mathrm{NH_3};$$

or by degradation to diffusible catabolites, for example, by nucleotidase activity:

$$\mathrm{AMP} + \mathrm{H_2O} \xrightarrow{\text{5'-Nucleotidase}} \text{Adenosine} + \mathrm{P_i}$$

In apparent deference to the latter, many mammalian erythrocytes have evolved nucleotidase isozymes that uniquely exclude AMP from their physiologic substrates.

The existence of a pyrimidine-specific nucleotidase (PyrNase) in human erythrocytes became apparent through investigation of patients with hereditary hemolytic anemia secondary to severe deficiency of that enzyme.[1] Initial studies of PyrNase properties in normal hemolysates indicated that AMP and other purine nucleotides were not effective substrates,[1,2] but that both purine and pyrimidine 2'-deoxyribonucleotides apparently were.[2] Dephosphorylation of some deoxy substrates was also detected in PyrNase-deficient cells[10,11] and subsequently proven to be due to deoxyribonucleotidase (dNase), a normal erythrocyte isozyme (or isozymes) distinct from PyrNase.[3]

In the interim, however, other investigators had observed that AMP could be degraded by hemolysates or partially purified preparations under specific in vitro conditions.[12,13] Resolution of these uncertainties regarding substrate specificity of PyrNase is important to understanding normal erythrocyte metabolism as well as molecular mechanisms of hemolysis in severe PyrNase deficiency states. PyrNase deficiencies are now recognized as among the more common enzymopathies responsible for hereditary hemolytic anemia and also contribute to the acquired anemia induced by lead toxicity.[14] Theoretically, a mutant PyrNase isozyme that also catalyzed dephosphorylation of AMP to diffusible adenosine might predominate over salvage reactions, such as that mediated by adenosine kinase, to cause an inexorable drain on the adenine nucleotide pool. Mechanisms other than mutant PyrNase, however, are required to explain apparent AMP dephosphorylation by normal erythrocytes.[13]

The present study provides some clarification of these conflicting observations. The data clearly establish that AMP is not a substrate for normal erythrocyte PyrNase, since cells from several subjects with severe PyrNase deficiency retained the same capacity to degrade AMP as normal and reticulocyte-rich specimens. This held true for IMP and dIMP, as well as for AMP, over a broad range of pH. These findings have been corroborated by supplementary studies with larger populations, using 12 different purine and pyrimidine ribo- and deoxyribonucleotides, which identified only UMP, CMP, and dCMP as direct substrates for normal erythrocyte PyrNase.[15]

The present study confirmed that AMP degradation may occur in human hemolysates, but that it is mediated by AMP-deaminase and dNase rather than PyrNase. Multiple paired experiments with normal red cells, young cell populations, and PyrNase-deficient cells indicated that rates of P_i evolution from AMP and IMP were virtually identical, regardless of pH (Fig 1). This would be expected if AMP were deaminated to IMP prior to dephosphorylation, an hypothesis that was confirmed by analysis of degradation products in incubated hemolysates (Table 1). Other studies have also shown that AMP-deaminase predominates over nucleotidase activity in certain leukocytes as well as erythrocytes, an imbalance that is pertinent to understanding intracellular accumulations of deoxynucleotides in severe combined immunodeficiency disease.[6]

It is interesting that the presence of coformycin, a potent inhibitor of adenosine deaminase, consistently increased IMP production from AMP more than fourfold at pH 7.2, presumably by stimulation of AMP-deaminase. Comparable increases in AMP-deaminase activity occurred when pH was shifted from 7.2 to 6.2. The mechanisms involved remain unknown but may relate to coformycin- or pH-induced alterations of secondary or tertiary structure of the enzyme protein that serve to increase its substrate avidity and catalytic effectiveness. Additional data, not included under Results, indicated that acidic pH protects both PyrNase and dNase from inactivation by lead, presumably by similar conformational changes that shelter sensitive sulfhydryl groups.

These studies demonstrate that AMP-deaminase and dNase combine to provide an effective pathway for AMP degradation in vitro, but the role of these enzymes in normal cellular metabolism remains unclear. If significant conversion of AMP to IMP were to occur in vivo, it would constitute a hazard equivalent to AMP dephosphorylation, since erythrocytes cannot resynthesize adenine nucleotides from IMP or dIMP[16] nor from the degradation products, inosine and hypoxanthine. A priori, then, this pathway cannot be highly active under normal in vivo circumstances, or the adenine nucleotide pool would be quickly depleted. Additionally, dNase activity is apparently insufficient physiologically to clear deoxyadenine nucleotides from cells of patients with severe combined immunodeficiency disease secondary to adenosine deaminase deficiency. The role of AMP-deaminase in such deoxynucleotide accumulation in the latter condition has been discussed in a separate study.[6]

It is tempting to speculate that the sharply acidic pH optima of AMP-deaminase and dNase suppress this pathway at physiologic pH but allow activation under specific circumstances. In the hypoxic, acidic environment of the spleen, for example, sequestered erythrocytes might progress rapidly from senescence to death via an accelerated drain on the adenine nucleotide pool mediated in part by these two enzymes. We have speculated previously[3,11] that dNase might serve physiologically to clear DNA degradation products from maturing erythroblasts and reticulocytes in a role analogous to that presumed for PyrNase in RNA catabolism.[1,11] If such were the case, it would be ironic that an enzyme essentially functioned only at the two extremes of the cell life span, mediating events both in maturation and demise. Such speculations may palliate the compulsion to seek purpose in Nature's design, but precise physiologic roles will more likely be revealed by future study of patients with specific deficiencies of these enzymes.

An Explanation for Nonimmunologic Adsorption of Proteins Onto Red Blood Cells: Schiff's Base Reactions

By D. Jamin, J. Demers, I. Shulman, H.T. Lam, and R. Momparler

During a phase I evaluation of diglycoaldehyde (INOX), an intravenous chemotherapeutic agent used to treat children with malignancies, all of eight patients tested developed a positive direct antiglobulin test (DAT) in vivo. The DAT became positive within one to seven days after the first administration of the drug and remained positive for up to 12 days following the last dose. The indirect antiglobulin tests were negative. None of the patients showed clinical or laboratory evidence of hemolysis at the time the DAT became positive or during follow-up. Eluates made from the red cells of two of the eight patients were both negative by indirect antihuman globulin testing. In vitro studies with INOX and glutaraldehyde, both dialdehyde compounds, showed nonimmunologic adsorption of protein onto red cells, probably by the condensation of aldehyde groups of these compounds to form Schiff's bases with amino acids of serum proteins and red cell membrane proteins. This reaction provides an explanation for the globulin detected on the red cells of patients treated with INOX.

© 1986 by Grune & Stratton, Inc.

INOX (diglycoaldehyde) is the periodate oxidation product of the purine nucleoside, inosine, in which carbons 2′ and 3′ have been oxidized to formyl groups (Fig 1A).[1,2] In vitro studies have indicated that the formyl groups can bind to proteins by a Schiff's type reaction and that this effect may be partly responsible for the antitumor properties of INOX.[3–5] During a phase I evaluation of INOX, all of eight patients tested developed a positive direct antiglobulin test (DAT). The DAT became positive within one to seven days after the first administration of the drug and remained positive for up to 12 days following the last dose. The indirect antiglobulin tests were negative. The possibility that INOX might have caused a nonimmunologic adsorption of serum proteins onto the red cells of the patients via Schiff's type reactions was investigated in a series of laboratory studies. Glutaraldehyde, a compound that forms Schiff's type reactions with proteins, was included in these studies.

MATERIALS AND METHODS

Patients. Direct antiglobulin tests were performed on the red cells of eight children before, during, and after the intravenous infusion of INOX in doses of up to 1,500 mg/m^2 per day for 4 to 10 days per course. The sex, age, and diagnosis of each patient is recorded in Table 1.

Materials. Routine techniques and commercially available reagents were used.[6] Reagents used included anti-IgG+C3b+C3d+C4 (Immucor, Norcross, Ga), anti-IgG (BCA, Malvern, Pa), anti-C3b+C3d+C4 (Ortho Diagnostics, Raritan, NJ), anti-bovine albumin (Cappel, Cochranville, Pa), anti-human albumin (Cappel), 22% bovine albumin (BCA; 22% bovine albumin was diluted to make 6% bovine albumin), 16 5% human immune serum globulin (Armour Pharmaceutical, Kankakee, Ill), 25% human albumin (Travenol, Glendale, Calif), and glutaraldehyde, 3000 ug/mL (Sigma, St. Louis, Mo). Inosine dialdehyde (INOX, NSC-118994) was supplied as a lyophilized powder by the National Cancer Institute.

Preparation of INOX solution. INOX was reconstituted in phosphate buffered saline (PBS), at either pH 7.0 or 7.4 to a final concentration of 132 mg/dL

Incubation of normal red cells with INOX plus selected protein media. One milliliter of normal cells was incubated at 37 °C for two hours with one mL of INOX, 132 mg/dL, plus one mL of either normal human serum, normal human plasma, 16.5% human immune serum globulin, 25% human albumin, 6% bovine albumin, or 22% bovine albumin. Red blood cells incubated with INOX and normal saline were used as a control. Following the incubation, the red cells were washed three times with normal saline and tested for cell-bound protein by antiglobulin and antialbumin tests using anti-IgG+C3b+C3d+C4, anti-IgG, anti-C3b+C3d+C4, antihuman albumin, and antibovine albumin

Incubation of normal red cells with glutaraldehyde and selected protein media. One milliliter of normal red cells was incubated at 37 °C for one hour with one mL of 300 mg/dL glutaraldehyde (either pH 6 5 or pH 7.4) plus one mL of either normal human serum, normal human plasma, 16.5% human immune serum globulin, 25% human albumin, 6% bovine albumin, or 22% bovine albumin. Red blood cells incubated with glutaraldehyde and normal saline was used as a control. Following the incubation, the cells were washed three times with normal saline and tested for cell-bound protein by antiglobulin and antialbumin tests using anti-IgG+C3b+C3d+C4, anti-IgG, anti-C3b+C3d+C4, antihuman albumin, and antibovine albumin.

Adsorption-elution studies. One milliliter of normal red cells was incubated for two hours at 37 °C with one mL of INOX plus one mL of 25% human albumin. The red cells were then washed six times with PBS (pH 7.4). The washed red cells were added to an equal amount of glycine buffer solution (pH 1.8). An eluate was obtained by spinning down this mixture and recovering the supernatant. Tris(hydroxymethyl)-aminomethane solution was used to neutralize the acidity of the eluate. The eluate pH was adjusted to 7.4 or 6 5 with 0.1N NaOH or 0.1N HCl.

One milliliter of the eluate was incubated with 0.1 mL of normal red cells at 37 °C for two hours. Following the incubation, the cells were washed three times with PBS, pH 7.4, and tested with antihuman albumin. Red cells incubated with human albumin alone and red blood cells incubated with INOX alone were used as controls.

Incorporation of radiolabeled INOX onto red cells. Radiolabeled 14C INOX was supplied by the Stanford Research Institute through Dr R. Engle of the National Cancer Institute. One milliliter each of red blood cells, normal plasma, and INOX-8-14C, at a concentration of 2 mg/mL (4.2 mCi/mmol, 14.2 microCi/mg) were incubated for up to 2 hours at 37 °C. At 5 minutes, 30 minutes, one hour, and two hours, 0.5 mL aliquots of the mixture were diluted with 6 mL of 0.9% NaCl, and centrifuged at 3,000 RPM for 5

†Greatest dilution of antiserum that gave macroscopic agglutination Normal red cells incubated in 16.5% human gamma globulin, 25% human albumin, or 6% and 22% bovine albumin without the addition of INOX were agglutinated by anti-IgG, antihuman albumin, and antibovine albumin, respectively, at dilutions of 1:2.

minutes. The precipitate was washed with 0.9% NaCl, centrifuged, and the supernatant discarded The washing was repeated two times Five mL of cold 5% trichloracetic acid were then added to the pellet; the mixture was centrifuged, and the supernatant discarded. The precipitate was washed in saline, and then suspended in 1 mL of NCS tissue solubilizer (Amersham) and incubated at 37 °C for 48 hours. A 0.2 mL aliquot of the solubilized material was placed on a GF/C glass fiber filter (2.4 cm in diameter), placed in Omnifluor Scintillation Fluid (New England Corp), and assayed for radioactivity using a Beckman 360 Scintillation counter. Red blood cells incubated with 5% dextrose and INOX were used as a control.

Grading and scoring. All grading of agglutination was in accordance with the technical manual of the American Association of Blood Banks.[6]

RESULTS

All eight patients developed a positive DAT within seven days after the first intravenous dose of INOX (Table 1). Heat prepared eluates were made from the red cells of two of the eight patients. Both of these eluates (pH approximately 7) were negative by indirect antihuman globulin testing. In patient #8 the DAT became positive following the first dose of INOX and in patient #4 remained positive for at least 12 days after the last dose of INOX. None of the patients showed clinical or laboratory evidence of hemolysis at any time; bilirubin concentration, hemoglobin concentration, and reticulocyte counts remained stable.

Table 2 summarizes the results of antiglobulin and antialbumin tests on normal red cells incubated with INOX and either normal human serum, normal human plasma, 16.5% human immune serum globulin, 25% human albumin, 6% bovine albumin, or 22% bovine albumin. The results were positive for all corresponding proteins except complement, and were stronger at pH 7.4 than at pH 7.0.

Table 3 summarizes the antiglobulin and antialbumin test results on normal red cells incubated at pH 7.4 with glutaraldehyde plus either normal human serum, normal human plasma, 16.5% human immune serum globulin, 25% human albumin, 6% bovine albumin, or 22% bovine albumin. The results were positive for all corresponding proteins except

complement. When the cells were incubated at pH 6.5, all reactions were negative.

Eluates prepared from red cells that had been incubated with human albumin plus INOX reacted with normal red cells using antihuman albumin when the pH of the eluate was 7.4 but not when the pH was 6.5. Control studies, ie, eluates at pH 7.4 prepared from red cells that had been incubated with human albumin without the addition of INOX were negative as well as acid eluates prepared from red cells that had been incubated with INOX and normal saline.

Fig 2 shows the uptake of radiolabeled INOX onto red blood cells.

DISCUSSION

Many drugs and chemicals are known to induce positive direct antiglobulin tests.[7] Drugs such as penicillin, quinidine, alpha-methyldopa, and cephalosporins have been well documented as causing positive direct antiglobulin tests in patients via a variety of mechanisms. None of these mechanisms is identical to that which is proposed to explain how INOX causes a positive direct antiglobulin test in vivo.

The positive antiglobulin and antialbumin tests induced in these studies demonstrate that INOX and glutaraldehyde can cause the adsorption of proteins onto red cells. The fact that albumin was adsorbed onto red cells from serum, plasma, or human or bovine albumin media in the presence of INOX or glutaraldehyde suggests that the mechanism is nonimmunologic. The proposed mechanism by which INOX and glutaraldehyde cause nonimmunologic adsorption of proteins onto red cells is via the formation of Schiff's bases.

INOX is the periodate oxidation product of the purine nucleoside, inosine, in which carbons 2′ and 3′ have been oxidized to formyl groups (Fig 1A).[1,2] Glutaraldehyde is similar in structure to INOX in that it also contains two free formyl groups (Fig 1B). In vitro studies have demonstrated that formyl groups can bind to proteins by a Schiff's type reaction.[3-5] Glutaraldehyde has previously been described as forming Schiff's type reactions with proteins.[8]

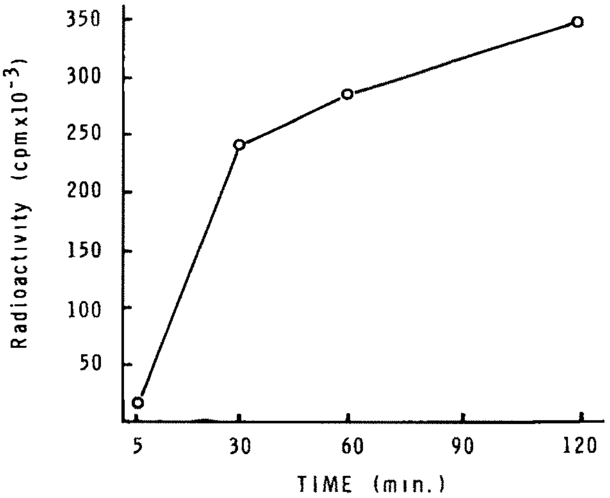

Fig 2. Incorporation of radiolabeled INOX into red blood cells. Radiolabeled INOX (2 mg/mL, 14.2 μCi/mg) was incubated with fresh plasma and red blood cells at 5, 30, 60 and 120 minutes; the radioactivity incorporated into the acid-insoluble fraction of red blood cells was determined.

Our hypothesis is that when red cells are incubated with either INOX or glutaraldehyde in an alkaline medium, one of the aldehyde groups of either INOX or glutaraldehyde forms a Schiff's base with an amino group of the red cell membrane. The other aldehyde group is free to form a Schiff's base with an amino group of a plasma protein. This proposed mechanism can explain the findings of a positive DAT in patients receiving intravenous INOX (pH of blood is 7.4) and the in vitro results described in this report. This hypothesis is supported by the observation that the adsorption of proteins onto red cells was pH dependent. Protein adsorption was detected when glutaraldehyde was used at a pH of 7.4 but not at a pH of 6.5. Less protein adsorption was detected when INOX was used at a pH of 7.0 than of 7.4. INOX and human albumin eluted from red blood cells could be readsorbed onto fresh red cells at a pH of 7 4 but not at a pH of 6.5.

Heat-prepared eluates from the red cells of two patients were nonreactive. A possible explanation is that the heat elution technique did not provide optimum conditions for the dissociation of INOX-immunoglobulin complexes from the patients' red cells or for the readsorption of those complexes onto red cells reacted with the eluate.

The findings in these experiments correspond with the behavior of Schiff's bases which are pH dependent, and easily hydrolyzed by acids.[9] The attachment of INOX to red blood cells is corroborated by the uptake of radiolabeled INOX-8-C14 by red cells using techniques similar to those reported by Kimball et al (Fig 2).[10]

INOX most likely acts to produce a positive DAT in vivo in a manner similar to the proposed in vitro mechanism, ie, by the condensation of an aldehyde group with amino acids of serum proteins and red cell membrane proteins to form Schiff's bases. Although immunoglobulin can be detected on the red cells of patients who have received intravenous infusions of INOX, the sensitization of these red cells does not appear to result in clinical evidence of hemolysis. This might be explained by the data that suggest that INOX results in the covalent attachment of immunoglobulin to red cells via the formation of Schiff's bases and not due to the specific interaction between the Fab portion of immunoglobulin molecules and red blood cells. The failure of immunoglobulin molecules to bind to red cells via their Fab portion could result in the inaccessability of the Fc portion of the immunoglobulin molecules to the Fc receptors present on macrophages, thus preventing both erythrocyte-macrophage interaction as well as hemolysis of the sensitized red cells.

INOX has not been used in phase I or II trials for five or six years and is not likely to be used widely in the future due to hepatic toxicity and relative ineffectiveness. However, these findings may be of potential practical importance since they offer a new explanation of how drugs can induce a positive direct antiglobulin test. In theory, any drug or chemical containing two or more aldehyde or acid groups capable of reacting with proteins under physiologic conditions could produce a positive direct antiglobulin test. Drugs or chemicals in this category include Evans blue, folic acid, maleic acid, glutaric acid, glyceryl trinitrate (nitroglycerin), menadiol sodium phosphate (synkavite), penillic acid, phthalic acid, picric acid, sodium iodipamide (cholografin sodium), and sodium iodomethamate (iodoxyl). Studies of these and other agents are being planned or conducted by our group.

ACKNOWLEDGMENT

The competent support of Jane Morita and Marcia Christen in typing this manuscript, Jacque Tagliere for serological testing and analysis, and Drs Kenneth Shaw and Gerald Endahl for biochemical consultation is most appreciated.

Synchronized Cultures of *P falciparum* in Abnormal Red Cells: The Mechanism of the Inhibition of Growth in HbCC Cells

By Julie A. Olson and Ronald L. Nagel

It has been previously demonstrated that HbCC cells fail to support growth of *P falciparum* in asynchronous Jensen-Trager cultures. To define the mechanism of inhibition we have studied synchronous cultures and found that while intraerythrocytic parasite development appeared normal, the liberation of merozoites and/or invasion was impaired. This effect was detected by a normal growth during the first growth cycle but dramatically reduced number of ring forms following the schizont stage. A specific test for the invasion of CC cells by *P falciparum* merozoites, nevertheless, was normal. The defect found in infected CC cells was not modified by changes in O_2 tension (which altered the ligand saturation of Hb C) nor by the extracellular K^+ concentration (excluding a K^+ leak-dependent mechanism for the growth inhibition). The osmotic lysis of late-staged parasitized red cells revealed that 25% of infected AA cells were lysed when the extracellular medium was 95 mOsm. In contrast, infected CC cells required a decrease to 10 mOsm in the extracellular media to reach 25% lysis. We conclude that CC red cells are unsuitable hosts for the malarial parasite primarily because of their inability to lyse and release merozoites at the appropriate stage of intraerythrocytic development of *P falciparum*.

IT HAS long been suspected that genetically abnormal human red cells found in individuals living in malaria endemic regions offer their carriers protection against mortality and morbidity from *P falciparum* infections.[1,2] Specifically HbC, the distribution of which is restricted to malaric areas in and around Upper Volta (Burkina-Faso) has been considered a malaria-selected red cell mutation although there is conflicting evidence.[3,4] In the last 5 years considerable understanding of the mechanisms involved in genetically determined cellular protection have been derived[5-8] from studies in cultures of the type described by Jensen and Trager.[9]

The objective of the present study was to determine the basis of the growth inhibition of *P falciparum* observed in red cells of individuals homozygous for HbC.[7] There are several stages in the erythrocytic cycle at which parasite infection could be inhibited. The first would be erythrocyte invasion by merozoites; several red cell membrane variants have been described that are refractory to merozoite invasion.[2,8] The next stage susceptible to inhibition is the intracellular parasite development. This category would include impairments in the parasite's ability to meet its nutritional requirements or changes in the host cell milieu that would be cidal to the parasite. G6PD deficiency and sickle cell anemia and trait, fall into this group.[10,11] Finally, impairment of red cell rupture and release of merozoites at parasite maturity could inhibit infection. No instances of this abnormality have yet been described.

We report here the invasion, effect of O_2, and extracellular K^+ level, and the consequence of the presence of the parasite on the osmotic response of HbC-containing cells, using synchronized in vitro cultures that mimic the growth pattern in the human infection. The data obtained strongly suggest that the mechanism involved in the HbC-containing cells is the impairment of the parasite's ability to produce cell lysis and the consequent unavailability of merozoites for further red cell infection.

MATERIALS AND METHODS

Cultivation of P falciparum. The FCR3 strain of *P falciparum* was maintained in culture[9] in synchronous growth[12] at 5% cell suspension, with daily replacement of medium.

Culture media. Unless otherwise stated, parasites were grown in RPMI 1640 (GIBCO, Grand Island, NY), 25 mmol/L HEPES (Sigma, St. Louis), 40 ug/mL gentamycin (Schering Pharmaceutical Corp, Kenilworth, NJ), and 10% (v/v) defibrinated human plasma (Jacobi Hospital Blood Bank, Bronx, NY). Such medium is referred to as RPS.

High potassium (HK) and low potassium (LK) media were prepared as described by Friedman et al.[11] In brief, all the components except the salts of the Selectamine RPMI 1640 kit (GIBCO) were combined. The medium was brought to 0.5 mmol/L $CaCl_2$, 0.4 mmol/L $MgCl_2$, 5.6 mmol/L Na_2HPO_4, and 0.2 g/L $NaHCO_3$. For HK, KCl was added to 105 mmol/L. LK was adjusted to 100.2 mmol/L NaCl and 5.4 mmol/L KCl. HEPES, gentamycin, and serum were added as for RPS.

Assessment of invasion. The susceptibility to merozoite invasion was assessed as described by Olson and Kilejian.[13] In 11 separate cultures (performed in triplicate) from 5 different HbCC donors, the proportion of invaded red cells was compared to invasion of HbAA cells in a parallel culture receiving the same inoculum.

Assessment of growth. Blood samples were collected into CPD and used within 2 weeks of collection. Hemoglobin composition was determined by cellulose strip electrophoresis (pH 8.6) and by Corning agar electrophoresis (pH 6.4). Just prior to infection, blood was washed in RPS without serum to remove the plasma and buffy coat. Cells were counted in a hemacytometer from duplicate dilutions and adjusted to 5×10^8 RBCs/mL (approximately a 1% cell suspension) in RPS. Inoculating parasites were obtained by gelatin enrichment[14] from schizont-containing cultures to greater than 60% parasitemia. Schizont-infected RBCs were added to test RBCs to achieve a final parasitemia of 1% (5×10^6 schizonts/mL). Samples were plated in 24 well Linbro plates (0.5 mL/well) and incubated under candle jar conditions unless otherwise indicated. Cultures grown in "3% O_2" were incubated in a gas mixture 3% O_2, 3% CO_2, 94% N_2, and at "17% O_2," in a mixture of 17% O_2, 3% CO_2, 80% N_2.

After 24 hours of growth (ie, through the first invasion), the culture medium was changed, either to HK, LK, or RPS, as indicated. Thereafter, medium was changed daily. Every 24 hours after infection, from each sample, 3 wells were collected to each of

three 12 × 75 mm tubes, centrifuged, and adjusted to approximately 50% cell suspension by removal of the medium. The suspensions were mixed, smeared, fixed in methanol, stained in Giemsa, and the % parasitemia determined by counting 1000 cells from each of the three smears for each sample Percentage of parasitemia is expressed as the average of the three determinations ± SEM.

Red cell volume determinations. Red cell volume (MCV) was calculated from triplicate cell counts in a hemacytometer and hematocrit (International, Microcapillary centrifuge) as follows. 1/(cells/mL − % hematocrit).

Osmotic sensitivity determinations Washed RBCs from HbAA or HbCC donors were inoculated with gelatin-enriched schizont-infected RBCs to 5% parasitemia and plated at a 1% cell suspension. After 42 hours incubation under candle jar conditions (with a change of medium at 24 hours), cells were collected, centrifuged at 1000 × g for 5 minutes, the supernatant medium removed, and the cell pellet mixed on a vortex mixer. Twenty-five μL of cell pellet was transferred to the bottom of a 12 × 75 mm tube. Two volumes (50 μL) of hypoosmotic medium (see below) were added while the tube was being vortexed and the sample was immediately drawn into a Pasteur pipette, thin smeared, and dried under a stream of air Thin smears were fixed in methanol and stained in Giemsa. The % of lysed, infected RBCs was calculated by dividing the number of lysed, infected RBCs (schizonts and clusters of merozoites not enclosed within RBC membrane and schizonts within RBC membranes within which the pinkish, hemoglobin stain was not visible) by the total number of infected RBCs (lysed plus unlysed, ie, schizonts within RBC membranes within which hemoglobin staining was observed) Hypoosmotic media were prepared by diluting Dulbecco's PBS (290 mOsm) with water to the desired osmolarity.

RESULTS

When AA and heterozygous AC RBCs were compared under standard culture conditions (Fig 1), there was no significant difference in parasite growth between the two cell types. However, parasite growth was markedly inhibited in homozygous CC RBCs (Fig 1). Invasion of HbCC cells was 85.0% ± 14.8% SD (n = 11) of control invasion of HbAA cells. Parasite morphology in HbCC cells appeared normal on day 2. Inhibition of growth in HbCC cells was only apparent in the second cycle of development (days 3 and 4) and was manifested as a lack of increase of parasitemia. It was observed that, in the CC cultures depicted in Figure 1A, there were many degenerated schizonts and segmenters on day 3.

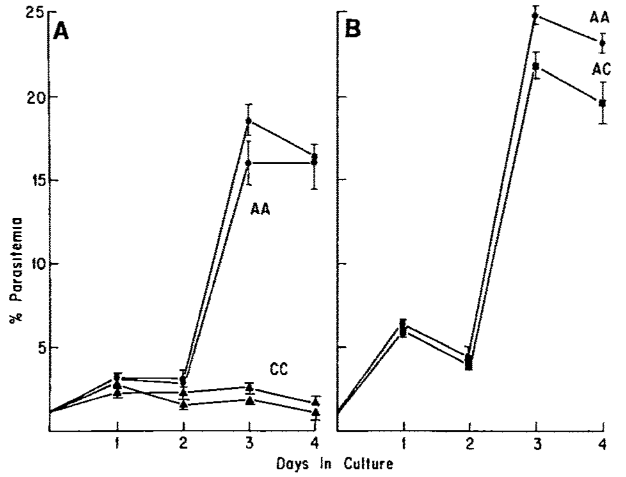

Fig 1. Synchronous growth of *P falciparum* in HbAA, HbAC, and HbCC erythrocytes at 17% O_2. Growth was assessed over four days (see Methods) in (A) 2 HbAA donors (closed circles) and 2 HbCC donors (closed triangles), and (B) a HbAA donor (closed circles) and a HbAC donor (closed squares).

To determine whether growth inhibition in CC RBCs resembles that in AS or SS RBCs,[11] growth was compared in high and low potassium media. Parasite growth in AA cells was consistently inhibited in high potassium medium (Fig 2, open *v* closed circles). Cultivation in the presence of high potassium medium did not reverse the inhibitory nature of CC cells (Fig 2, open *v* closed triangles); in fact, parasite growth was even further impaired in high potassium. MCV determinations indicated that incubation in high potassium medium did not alter red cell volume relative to that in low potassium medium in either AA or CC cells.

Cultivation of *P falciparum* in CC RBCs under conditions of low oxygen tension (3% oxygen) did not decrease the parasitemia, as is the case in AS and SS cells.[2] In fact, the parasitemia was slightly increased (Fig 3) in both AA and CC cells at low oxygen. Incubation in high potassium medium at low oxygen did not alter the pattern of growth in CC cells (data not shown).

The effects of changes in potassium content of the medium and oxygen tension during cultivation indicated that the mechanism of growth inhibition in CC cells did not resemble that in SS or AS cells.[11] However, since studies of *P falciparum* growth in AS and SS cells had been carried out

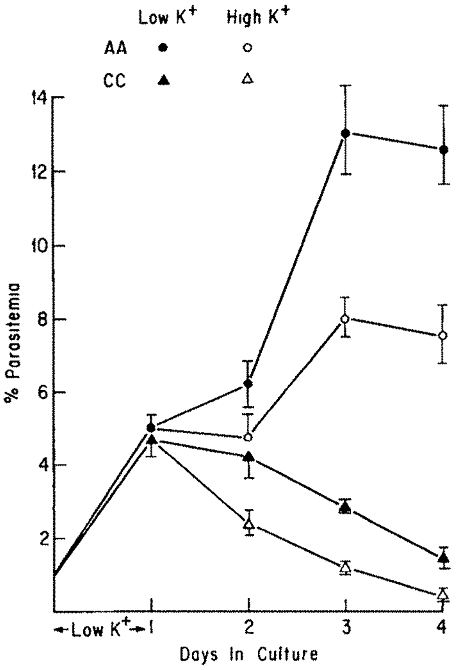

Fig 2. Synchronous growth of *P falciparum* in HbAA and HbCC erythrocytes in high and low potassium medium at 17% O_2. After merozoite invasion in low potassium medium (days 0 to 1), cells were transferred to high potassium medium (HbAA open circles, HbCC open triangles) or low potassium medium (HbAA closed circles, HbCC closed triangles) and growth was assessed for the following 3 days.

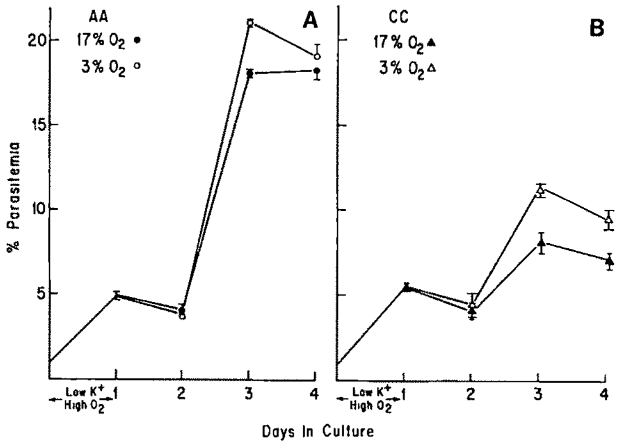

Fig 3. Synchronous growth of *P falciparum* in (A) HbAA and (B) HbCC erythrocytes at high (17%) and low (3%) oxygen tension in low potassium medium. After merozoite invasion at 17% O_2 (day 0 to day 1), cultures were transferred either to 17% O_2 (HbAA closed circles, HbCC closed triangles) or 3% O_2 (HbAA open circles, HbCC open triangles) and growth was assessed for the following 3 days.

in asynchronous cultures, it was deemed important to repeat these experiments under conditions of synchronous growth and to follow the complete course of growth over 4 days. Fig 4 depicts the results of experiments in which parasite growth over a four-day period was assessed in AA (Fig 4A), SS (Fig 4B), and AS (Fig 4C) cells under conditions of high and low potassium and high and low oxygen. As noted above (Fig 2), parasite growth was inhibited in AA cells in high potassium, both at high and low oxygen (Fig 4A). In addition, growth was increased at low oxygen.[15] Unlike parasite growth in CC cells, growth was almost normal in both AS and SS cells at high oxygen (Fig 4B and 4C, closed circles). In both AS and SS cells, growth was reduced in the presence of high potassium media at high oxygen (Figure 4B and 4C, closed triangles). At low oxygen tension, parasite growth in SS cells was severely inhibited (Figure 4B, open circles) and the inhibition was not reverse by cultivation in the presence of high potassium medium (Figure 4B, open triangles). However, in AS cells, the inhibition of growth at low oxygen (Figure 4C, open circles) was reversed by incubation in high potassium medium (Figure 4C, open triangles). This reversal was most apparent on day 3.

The observation that segmenters remained in the CC culture on day 3 (Figure 1A), taken in conjunction with the known osmotic resistance of CC cells,[16] led us to postulate that parasites that had developed in CC cells were not able to overcome the osmotic barrier, and hence could not release merozoites at the appropriate time. Osmotic resistance in *Plasmodium*-infected CC cells has not been studied. The experiment illustrated in Fig 5 was designed to observe osmotic sensitivity of infected cells in a mixed population of infected and uninfected cells. The L25 (osmolarity of added media at which 25% of the infected cells were lysed) for AA cells was approximately 95 mOsm and for CC cells was 10 mOsm.

DISCUSSION

There are several properties of HbC-containing cells that could protect against *P falciparum* infection. First, the cells have a decreased deformability. In some cases, cells with reduced deformability are refractory to invasion.[17,18] Second, CC cells are hyperdense and can even contain intracellular crystals of hemoglobin.[19] Such properties could impair the parasite's ability to develop within the cells, in much the same way that *P falciparum* growth is inhibited in HbS polymer–containing cells.[6] In addition, the reduction in cation content (Na^+, K^+),[20] could have a deleterious effect on parasite development. Third, CC cells are osmotically resistant,[16] and might trap the parasite by inhibiting host cell rupture.

The reduced deformability and suspected membrane changes in HbCC cells[21] do not appear to interfere with merozoite invasion, as demonstrated here. Furthermore, development of the parasite through schizogony appears to be identical to that in HbAA cells under all conditions tested here. The possibility that slight inhibition of intracellular parasite development also makes a minor contribution to the abnormal growth pattern in CC cells cannot be rigorously excluded without additional studies demonstrating normal metabolic junctions (hypoxanthine incorporation, amino acid incorporation, glucose utilization, etc) during schizogony. Cytosol phase conditions (ie, presence or absence of aggregated hemoglobin C) and potassium concentration in HbCC cells do not seem to influence intracellular development, in contrast to the findings in HbSS and HbAS erythrocytes restudied here (Fig 4).[11] We have reexamined the growth curve of *P falciparum* in AA and AS cells in

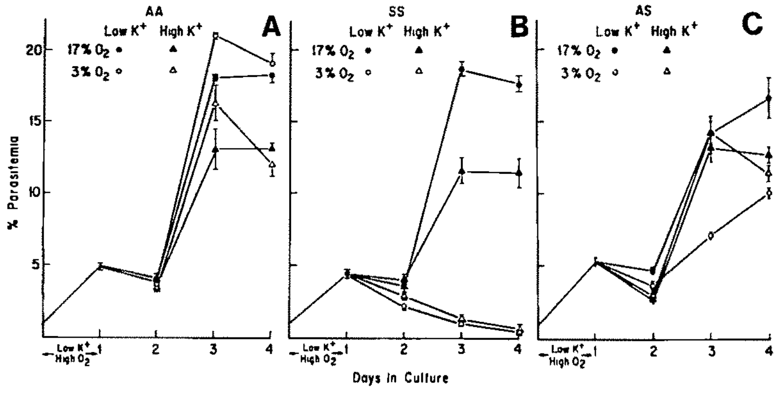

Fig 4. Synchronous growth of *P falciparum* in HbAA, HbAS, and HbSS erythrocytes at high and low O_2, and in high and low potassium medium. After merozoite invasion in low potassium medium at 17% O_2, cultures were transferred to high or low potassium medium and high or low O_2. (A) HbAA, (B) HbSS, and (C) HbAS. Closed circles—low potassium and 17% O_2, open circles—low potassium and 3% O_2, closed triangles—high potassium and 17% O_2, open triangles—high potassium and 3% O_2.

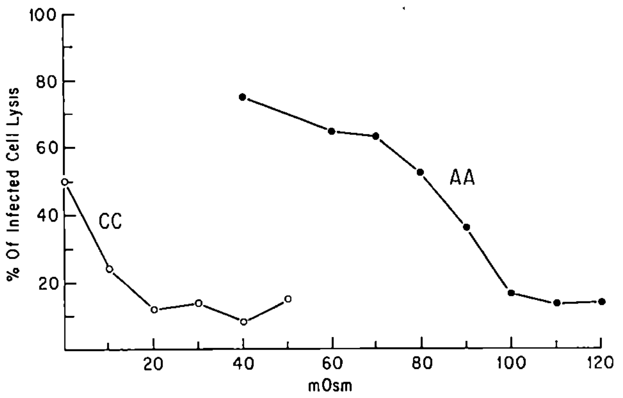

Fig 5. Osmotic sensitivity of *P falciparum* schizont-infected HbAA and HbCC erythrocytes. Osmotic lysis of infected HbAA (closed circles) and HbCC (open circles) was assessed as described in the Methods. The abscissa shows the osmolarity of buffer added to infected cell pellets.

synchronized cultures and have confirmed results obtained from asynchronous cultures.[11] Parasite growth in SS and AS cells is only impaired under conditions of low oxygen tension. At low oxygen and at the lowered intracellular pH of infected SS cells, HbS polymerizes and the parasite is probably killed by an inability to use this polymerized hemoglobin as a food source[22] and mechanical rupture of the parasite by HbS polymers.[23]

In AS cells, parasite growth is inhibited at low O_2 and normal growth is restored in a high K^+ medium. The mechanism of the growth inhibition in AS cells could be an intrinsic sensitivity of the parasites to a low K^+ environment or that K^+ leak-induced dehydration (coupled with increased intracellular pH) could increase intracellular polymer formation, which in turn, as in the case of SS cells, might not be a good substrate for the parasite proteases.[22] The high K^+ medium then, by inhibiting K^+ egress, restores normal growth.

We turn now to CC cells. First, unlike AS and SS cells, parasite growth was inhibited at high oxygen. In fact, at low oxygen, CC cell growth was slightly enhanced, as in AA cells. Second, incubation in high potassium did not restore normal growth. In fact, high K^+ (105 mmol/L) was inhibitory relative to normal low K^+ (5.4 mmol/L) medium, both at high oxygen and at low oxygen. We can conclude from these observations that the mechanism of inhibition of *P falciparum* growth in CC cells does not involve loss of K^+ and subsequent dehydration.

The observation that many degenerating schizonts are detected on day 3 in the CC cultures (and even on day 2), combined with the observed high osmotic resistance of parasitized CC cells (Fig 5), suggest that these abnormal cells represent too great a barrier for the parasite to overcome in the process of host-cell rupture. The mechanism of parasite-induced red cell lysis is probably a combination of well-known increases in host cell membrane permeability during parasite development[24] and the possible participation of parasite proteases and lipases that attack the membrane. The role in parasite growth inhibition played by the membrane transport abnormalities recently reported in CC cells[25] are yet to be determined.

The normal parasite growth in AC cells can be readily understood, in the context discussed, by the fact that they exhibit a much less abnormal osmotic lysis curve than CC cells, particularly between 95% and 100% lysis. At this range, AC cells are lysed at the same osmotic environment as AA cells.[16]

It is appropriate to point out that although AC cells appear to sustain normally the growth of *P falciparum,* this does not exclude the possibility that these cells could offer the carriers fitness advantages by other mechanisms. For example, AC individuals might have retardation of the switch from Hb F to A in the critical first years of life. As Hb F–containing cells do not sustain parasite growth normally,[26] the carrier can be rendered significantly resistant to the disease. In addition, in vitro growth experiments do not model all of the pathologic events in vivo. For example, it is possible that infected AC cells have abnormal membrane knobs that might alter knob-mediated deep vascular schizogony,[27] although data are not available to prove the advantage of AC individuals in malaric regions. These are difficult experiments, and a final conclusion should wait for further investigation.

We conclude that while AC cells sustained normally the growth of *P falciparum* in vitro, CC cells do not allow normal development of the parasite, primarily because the abnormal osmotic response of parasitized CC cells interferes with red cell rupture needed for the liberation of infective merozoites.
